THE NASA STI PROGRAM OFFICE . . . IN PROFILE

Since its founding, NASA has been dedicated to the advancement of aeronautics and space science. The NASA Scientific and Technical Information (STI) Program Office plays a key part in helping NASA maintain this important role.

The NASA STI Program Office is operated by Langley Research Center, the lead center for NASA's scientific and technical information. The NASA STI Program Office provides access to the NASA STI Database, the largest collection of aeronautical and space science STI in the world. The Program Office is also NASA's institutional mechanism for disseminating the results of its research and development activities. These results are published by NASA in the NASA STI Report Series, which includes the following report types:

- TECHNICAL PUBLICATION. Reports of completed research or a major significant phase of research that present the results of NASA programs and include extensive data or theoretical analysis. Includes compilations of significant scientific and technical data and information deemed to be of continuing reference value. NASA's counterpart of peer-reviewed formal professional papers but has less stringent limitations on manuscript length and extent of graphic presentations.

- TECHNICAL MEMORANDUM. Scientific and technical findings that are preliminary or of specialized interest, eg, quick release reports, working papers, and bibliographies that contain minimal annotation. Does not contain extensive analysis.

- CONTRACTOR REPORT. Scientific and technical findings by NASA-sponsored contractors and grantees.

- CONFERENCE PUBLICATION. Collected papers from scientific and technical conferences, symposia, seminars, or other meetings sponsored or cosponsored by NASA.

- SPECIAL PUBLICATION. Scientific, technical, or historical information from NASA programs, projects, and mission, often concerned with subjects having substantial public interest.

- TECHNICAL TRANSLATION. English-language translations of foreign scientific and technical material pertinent to NASA's mission.

Specialized services that complement the STI Program Office's diverse offerings include creating custom thesauri, building customized databases, organizing and publishing research results . . . even providing videos.

For more information about the NASA STI Program Office, see the following:
- Access the NASA STI Program Home Page at http://www.sti.nasa.gov
- E-mail your question via the Internet to help@sti.nasa.gov
- Fax your question to the NASA Access Help Desk at (301) 621-0134
- Telephone the NASA Access Help Desk at (301) 621-0390

1 *Executive Summary*

This test was a continuation of Integrated Suit Tests (IST) 1 and 2 (1) (2). The main objective was to investigate the effects of varying center of gravity (CG) locations on human performance in the suited and shirt-sleeve condition; however, due to facility limitations only the shirt-sleeve condition was evaluated. Although there were different performance results between CGs, the data analysis seems to indicate that many of the observed differences may have been the result of system dynamics, hardware setup, and/or testing methodology, rather than a direct result of the system CG location in relation to the subjects' CG.

Three of the CG configurations unexpectedly had almost identical metabolic values. One CG configuration led to significantly greater metabolic rates than all other configurations, however, this was likely due to system configuration issues and not because it was a poor CG location. Overall, the lack of variability between the other three CG configurations indicates that either there were no notable differences in human performance among these CG configurations or other factors may have compromised the ability to effectively vary CG using an overhead suspension lunar gravity simulator. Possible solutions to this issue include improvements to the lunar analog facility and the to the gimbal support structure used to interface subjects to the facility for testing.

Metabolic and subjective results among CG conditions for ambulation were very similar and lead to the same conclusions. Biomechanics results were more variable in interpretation. One important finding was a high degree of variability among subjects for both the exploration tasks and the postural control test. This highlights the need to test a greater number of subjects and to thoroughly characterize the subject pool so that aspects of their anthropometry, strength, and/or fitness can be analyzed to determine if these underlying subject characteristics had a significant effect on their performance.

In addition to the standard end of trial determination of Ratings of Perceived Exertion (RPE) and the Gravity Compensation and Performance Scale (GCPS), subjects also provided these ratings at the 30-s mark shortly after each trial began. Results indicated that GCPS had less variability between the early and end of trial measurements, with 82% of trials showing no change compared to 68% for RPE. The majority of RPE and GCPS results that did change increased by only 1 unit on the rating scale (26% for RPE, 12% for GCPS). Although not conclusive, it does show promise for using both of these ratings with nonsteady-state tasks and in environments that preclude direct metabolic measurement.

The Space Vehicle Mockup Facility's (SVMF) partial gravity simulator, known as "POGO", provides a reasonable ground-based analog for testing postural stability during reduced-gravity loading; however, its mechanical couplings limit observations to a single plane of motion (sagittal) and its upward force vector may have a mechanical and/or physiologic (haptic) stabilizing influence on balance control that could reduce apparent instabilities, particularly in body sway displacement.

Postural stability appeared to be degraded during the simulated reduced-gravity loading conditions tested in this experiment, and the performance patterns suggest that somatosensory information may be degraded in hypogravity environments. We recommend that follow-up experiments be performed, probably during parabolic flight, to verify these findings without the potential mechanical-based confounding factors of the POGO system.

2   Introduction

Analysis of video from Apollo lunar surface extravehicular activities (EVAs) has demonstrated that astronauts experienced difficulty maintaining stability. This led to the hypothesis that space suit CG is an important parameter affecting human performance. To specifically evaluate the role of CG, tests have been performed at the Neutral Buoyancy Laboratory (NBL) and during NASA Extreme Environment Mission Operations (NEEMO). Initially, six configurations that framed the boundaries of potential CG location (high, low, aft, forward, ideal, and the Crew and Thermal Systems Division [CTSD] 2005 'baseline' CG) were evaluated for their effect on ambulation and performance of exploration tasks. Based on crewmember GCPS ratings, these studies demonstrated that the ideal and forward CGs were acceptable (3). The others required moderate to considerable operator compensation, with the high and aft CGs being the least favorable. Subsequent NEEMO tests evaluated four additional CG configurations located within the region that is expected to contain the lunar spacesuit system CG. Preliminary unpublished results indicated that these CG locations were acceptable based on crew GCPS ratings.

Although an insightful first look at the effect of CG on human performance in lunar gravity, the underwater environment does not permit several critical data parameters such as metabolic rate and biomechanics to be collected. The purpose of this study was to expand on the preliminary CG research from the underwater environments and evaluate the effects of varying CG on human performance in lunar gravity using the Johnson Space Center (JSC) SVMF partial gravity offload system (POGO) with unsuited subjects.

2.1   Test Objectives

The primary objective of this study was to evaluate if and how a change in system CG affects human performance metrics (eg, metabolic rate, biomechanics, subjective ratings, stability) in simulated lunar gravity during level ground ambulation, inclined ambulation, exploration tasks and postural testing.

It should be noted that this objective was to be tested in both the unsuited and suited condition, but was only tested in the unsuited condition. The POGO, in its current configuration, could not offload the additional weight required to complete the test in the suited condition (with the MK III suit system as described in the IST-1 final report (1) and the new CG rig); therefore, the planned objectives for the suited condition were deleted from this test.

3   Methods

3.1   Subjects

The subjects tested were all male crewmembers recruited from a group of astronauts selected to support exploration EVA studies. At the time of subject selection, the suited portion of the test was expected to be completed; therefore, only those who had a known acceptable suit fit in the MKIII were considered for inclusion because of potential medical safety issues. At the time of testing, no available female astronauts properly fit in the MKIII suit.

Over the course of the study, a total of seven subjects participated with five of these subjects participating in all portions of the testing protocols. Of the two remaining subjects, one subject performed only the ambulation portion of the study and the other subject performed only the postural stability and exploration tasks. The means and standard deviations for the ambulation subject statistics

are mass 83.2 ± 8.7 (kg), height 181.8 ± 6.8 (cm), and age 50 ± 5 (yr). Figures 3-1 and Figure 3-2 show the population distribution of these test subjects compared to NASA's Human Systems Integration Requirements (HSIR) database for stature and mass. The means and standard deviations for the postural stability and exploration tasks subject statistics are mass 78.1 ± 7.4 (kg), height 179.5 ± 6.2 (cm), and age 49 ± 6 (yr). As shown, the distribution of the subjects for stature is skewed to the upper end of the database for both the male distribution. The distribution of the subjects for mass is relatively centered for the male distribution.
Figure 3-1. The subject population distribution for stature (cm) against the HSIR database.
Figure 3-2. The subject population distribution for body mass (kg) against the HSIR database.

As stated, no female subjects participated in this study. It should also be noted that there have been several research studies that have shown that there are biomechanical differences between males and females with one study showing interesting differences between males and females while carrying loads (4). Therefore, results and conclusions should be only considered valid for males.

3.2 Hardware

3.2.1 Partial Gravity Simulator (POGO)

All reduced-gravity simulations during IST-3 were performed using the SVMF POGO system. The POGO system has been previously described in the EVA Walkback Test final report (5). The gimbal support structure also described in that paper was customized for specific IST-3 applications and will be discussed separately.

3.2.2 Gimbal Support Structure with Adjustable CG Rig

The gimbal support structure has been described in the EVA Walkback Test and IST-1 Reports (1) (5). To alter the system CG, the gimbal support structure, previously only used for suited applications, was modified in two major ways. The first was a modification to support shirt-sleeve subjects by attaching a harness (Amspec # JV0100P, Van Nuys, CA) also know as a "jerk vest" to a flat metal plate rigidly connected to the gimbal. The leg straps of the harness were modified such that webbing was sewn to

the leg straps that pulled them together and created a "seat" to improve comfort and remove an artifact of the leg straps that tended to pull subject's legs apart. Velcro® was also added to the leg straps to keep the straps securely tight during trials.

Figure 3-3. Shirt-sleeve harness (Amspec #JV0100P) showing additional modifications to the leg straps.

The second modification was the addition of an adjustable CG rig with support arms that allowed adjustment of system CG by the addition to and variable positioning of weights on the support arms. In addition to the movement of the weight support arms and the weights, the system CG was also adjustable by moving the "stinger" horizontally through the gimbal support structure or vertically through the connection to the adjustable CG rig. The gimbal support structure with adjustable CG rig is shown in Figure 3-4 with the stinger adjustments shown in more detail in Figure 3-5.
Figure 3-4. Gimbal support structure with adjustable CG rig (offset view).
Figure 3-5. Stinger interface to gimbal support structure and adjustable CG rig.

Initial prototypes of the adjustable CG rig had the shirt-sleeve harness attached directly to a metal plate that ended just above the gluteus maximus for the modeled subject with a height of 182.9 cm. Upon testing the harness, this location for the edge of the plate proved unsatisfactory because it rested painfully across the lower back and posed a safety risk. A portion of the bottom of the plate and plate

support structure was removed such that the bottom of the plate was now equivalent with the navel height. Rigid foam padding was then inserted in place of the previously existing plate such that it contacted the subject's lower back and top of the gluteus maximus. This rigid padding allowed for comfortable contact between the subject and CG rig and provided a greater surface area of contact so that the subject's movements more easily translated into movement of the gimbal support structure and CG rig. These changes are shown in Figure 3-6.
Figure 3-6. CG rig adjustments for subject comfort and controllability.

To keep the subject rigidly connected to the adjustable CG rig, hardware slid through the pickup points on the back of the shirt-sleeve harness and bolted directly to the back plate of the adjustable CG rig. Adjustable straps were then connected to two different locations on each side of the shirt-sleeve harness and the adjustable CG rig. These straps were pulled tight to allow the subject's movement to transfer directly into the gimbal rather than having the subject moving independently of the gimbal (see Figure 3-6).

3.2.3 VacuMed Oversized Treadmill

The VacuMed large research treadmill (VacuMed, model #13610, Ventura, CA) was used for all treadmill testing. This treadmill was previously described in the IST-1 final report (1).

3.2.4 PRO Balance Master®

The PRO Balance Master® (Neurocom International, Inc., Clackamas, OR) provides objective assessment and retraining of the sensory and voluntary motor control of balance on either a stable or unstable support surface (see Figure 3-7). The system consists of a dual-force plate (18 in. × 18 in.), electronic control module and computer. The dual-force plate measures the distribution of forces exerted by the feet against the support surfaces. The electronic control module consists of the force

transducer amplifiers, force plate servo controls, platform-computer interface, and associated power supplies. The Balance Master® computer executes the test protocols, servo commands, and displays. The subject is placed atop the platform, and the ankle joints are aligned with the rotational axis of the support surface. The platform is designed to provide sway referencing in the anterior-posterior (AP) direction, and returns to a level starting position in between trials.

Figure 3-7. PRO Balance Master® system.

3.3 Testing Configurations

3.3.1 Center of Gravity Locations

Four different system CG locations were tested during IST-3. CG locations will be defined throughout this report as the distance between the subject's CG and the overall system CG that includes the subject, gimbal support structure, and adjustable CG rig. Table 3-1 shows the amount that the system CG was offset from the subject's CG. Negative values in the "Fore/Aft Offset" column indicate that the CG was behind the subject's CG. Positive values in the "High/Low Offset" column indicate that the CG was higher than the subject's CG. CG offsets were set using a 189.9 cm (72 in.), 81.6 kg (180 lb) male human computer model; therefore, CG offsets will vary slightly between subjects as their anthropometrics vary from the human computer model. Table 3-1 shows both the target offsets and the actual achieved offsets. Although achieved offsets were very close to the targeted offsets, there were slight differences due to the inability to adjust the spider vertical and horizontal adjustments by anything less than 1.27 cm (0.5 in.) increments. Figure 3-8 shows a lateral view of each CG configuration and Figure 3-9 shows an anterior view.

Table 3-1. System CG locations

CG Configuration	Target Fore/Aft Offset	Target High/Low Offset	Achieved Fore/Aft Offset	Achieved High/Low Offset
Perfect	0.0 cm	0.0 cm	0.2 cm	-0.2 cm
Backpack	-4.8 cm	1.0 cm	-4.9 cm	1.1 cm
CTSD	-7.6 cm	14.4 cm	-7.4 cm	13.7 cm
POGO	-11.2 cm	20.1 cm	-10.6 cm	20.1 cm

Figure 3-8 shows a lateral view of each CG configuration and Figure 3-9 shows an anterior view. Note the relationship of the subject to the gimbal axes of rotation, the height horizontal arms of the CG rig and the fore/aft distance of the lead weights on the horizontal arms. As the subject moves forward of the gimbal axes of rotation and/or the weights are moved aft on the horizontal arms, the system CG was moved aft. As the gimbal is raised in relation to the subject or if the horizontal arms are elevated, the system CG was moved high.

Perfect

Backpack

CTSD

POGO
Figure 3-8. Lateral view of each CG configuration.

Perfect   **Backpack**

CTSD   **POGO**
Figure 3-9. Anterior view of each CG configuration.

The perfect CG was chosen because it represents the ideal condition of adding significant mass to the subject in perfect proportion such that it does not alter the subject's own CG. The Backpack CG was chosen because it represented a potential option based on current suit and Portable Life Support System (PLSS) modeling. The CTSD CG was the CG of the suit and PLSS as defined in 2005. The POGO CG was determined to be the system CG as tested during previous suit tests including the EWT (5), IST-1 (1) and IST-2 (2).

In addition to achieving the correct CG offset from the system CG to the subject's CG, the system CG also needed to be co-located with the gimbal axes of rotation so as not to introduce any artificial rotational moments. Positioning of the CG rig and subject was performed so that the system CG was co-located as close as possible to the gimbal axes of rotation. Preliminary model calculations placed the system CG within 0.1 cm of the gimbal axes of rotation with the exception of the CTSD CG, which had the system CG 0.6 cm aft of the gimbal axes of rotation.

3.3.2 Offload Profiles

There were three different offload profiles used during this study. The first profile involved no offload, with the subjects performing all tasks in 1-g with no CG rig and not connected to the POGO (1-g). The second profile had the subject don the CG rig at the Perfect CG, but with the weight of the CG rig offloaded, so that the subject's total gravity adjusted weight (TGAW) was the same as the first profile, their 1-g body weight (1-g [Perfect]). TGAW is defined as the weight remaining on the ground and is the product of the total system mass and the offload level. The third profile had the subject don the CG rig and then the total system mass (combined mass of the subject, gimbal, and CG rig) was offloaded to represent lunar gravity (1/6-g) (Perfect, Backpack, CTSD, POGO).

3.3.3 Test Configurations

A total of 6 different CG/offload configurations were tested. They are described in Table 3-2 based on the reference subject's body mass of 81.6 kg. Each subject's actual TGAW varied slightly depending on respective differences from the reference subject.

Table 3-2. Test Configurations

Configuration Name	CG Fore/Aft Offset (cm)	CG High/Low Offset (cm)	Subject Mass (kg)	Gimbal/CG Rig Mass (kg)	Intended Offload	TGAW (N)	TGAW (lb)	Conditions Tested
1-g	N/A	N/A	81.6	0	1-g	800	180	All
1-g (Perfect)	0.2	-0.2	81.6	111	Weight of CG rig offloaded	800	180	Posture and Exploration Tasks
Perfect	0.2	-0.2	81.6	111	1/6-g	315	71	All
Backpack	-4.9	1.1	81.6	111	1/6-g	315	71	All
CTSD	-7.4	13.7	81.6	111	1/6-g	315	71	All
POGO	-10.6	20.1	81.6	111	1/6-g	315	71	All

3.3.4 Test Order

Initially, the test order was to have all subjects perform the tasks in the 1-g configuration followed immediately by the 1-g (Perfect) configuration. After trying to do this with 2 subjects, it was determined that the 1-g (Perfect) configuration was too difficult for the treadmill tasks and incurred an unacceptable safety risk to the subject. Therefore, that configuration was not used for the remainder of the ambulation trials, although it was used for the exploration and postural stability tasks. It was also assumed that the high and aft CG configurations (CTSD and POGO) would be more difficult, so for each treadmill test day, the subject completed both the level and incline conditions with either the CTSD or POGO CG and either the Perfect or Backpack. With the exception of placing the 1-g trial at the beginning for the purposes of defining a baseline, all CG configurations were done in a balanced order to minimize possible learning and or fatigue issues for the treadmill days. For each CG/offload configuration on the treadmill testing day, the level conditions were completed first and then the incline conditions were completed after a rest period. For the posture and exploration tasks test day, the order of the first 3 configurations was fixed as 1-g, 1-g (Perfect), and Perfect. The remaining CG configurations were

completed in a balanced order. For the posture and exploration tasks days, the postural stability testing was done first immediately followed by the exploration tasks.

Table 3-3. Test day and CG condition order.

	Sub 1	Sub 2		Sub 3	Sub 4	Sub 5	Sub 6
Day 1 - Treadmill	1-g	1-g	Day 1 - Treadmill	1-g	1-g	1-g	1-g
	1-g (Perfect)	1-g (Perfect)		CTSD	POGO	Backpack	POGO
Day 2 - Treadmill	Backpack	Perfect		Perfect	Perfect	POGO	Backpack
	CTSD	CTSD	Day 2 - Treadmill	Backpack	CTSD	Perfect	CTSD

	Backpack	Backpack					

3.4 Test Protocols

3.4.1 Level Ambulation

All level ambulation was performed on a treadmill with the grade set to 0%. Treadmill speeds were 0.4, 0.8, 1.3, 1.7, 2.1, and 2.5 m•s^{-1}. Time at each speed was 3 min. For each condition, subjects started at the lowest speed and proceeded continuously to the fastest speed.

3.4.2 Graded Ambulation

All graded ambulation was performed on a treadmill with the speed set to 0.8 m•s^{-1}. This speed was selected to overlap with one of the level ambulation speeds and seemed a reasonable estimate of the speed that an astronaut might walk up and down slopes during lunar EVA. Treadmill grades were -10, 0, 10, 20, and 30% incline. Time at each grade was 3 min. For each condition, subjects started at the decline and proceeded incrementally to the highest incline. Because of equipment calibration needs, a short break of approximately 1 to 2 min was required between each incline stage. Although part of the graded ambulation data set, the actual completion of the 0% incline stage occurred during the level ambulation data collection.

3.4.3 Exploration Tasks

Subjects performed three distinct exploration tasks representing typical activities expected during lunar EVA operations. All tasks were short in duration, lasting only a few seconds to complete. This was intentional to be able to compare results to a concurrent study using similar techniques during parabolic flight (6).

1. Rock pick-up – Subjects stepped onto two force plates with one foot on each force plate and got into a steady position. Then, they bent down to pick up a 2.7 kg lead shot bag and then stood up completely. Subjects then returned the bag to the starting point, stood back up and stepped off the force plates. To be consistent with previous studies, the bag was elevated on a surface 50 cm from the top of the force plates (2).
2. Shoveling – Subjects were provided a shovel before the beginning of this task. Subjects then stepped onto two force plates with one foot on each force plate and got into a steady position. Then, they proceeded to shovel a 2.7 kg lead shot bag from the 50 cm elevated surface and then dump the bag on the floor. Once the single shovelful was transferred, subjects stepped off the force plates. To be consistent with previous studies, the bag was elevated on a surface 50 cm from the top of the force plates (2).
3. Kneel and recover – Subjects kneeled down on one knee and returned to a standing position. Subjects always kneeled down on the right knee.

3.4.4 Postural Stability

Postural stability testing was performed with the subject standing quietly on a computerized dynamic posturography (CDP) system force plate (support surface) with arms folded across the chest. The subject was asked to maintain stable, upright stance under two 100-s duration quiet stance conditions: Sensory Organization Test (SOT) 1, a standard clinical Romberg test condition with eyes open and fixed support surface, and SOT 4, a test identical to SOT 1, except somatosensory inputs were distorted by sway-referencing (rotating about the ankle joint in direct proportion to the instantaneous center-of-mass sway angle) the support surface. Following the two quiet stance conditions, the subject was asked to maintain stable, upright stance throughout a series of six 10-s duration motor control tests (MCT), each challenging the posture control system with a sudden toes up (TU) or toes down (TD) rotation (840-ms rest, 8°/160 ms-perturbation, 9-s recovery). The six trials consisted of three TU trials and three TD trials presented according to a randomized schedule for each configuration.

3.5 Metabolic Data Collection and Analysis

During all ambulation testing, metabolic rate was determined from the continuous measurement of oxygen consumption (VO_2), carbon dioxide (CO_2) production, and expiratory volume (V_E) using an oronasal mask with the COSMED K4b[2] (COSMED USA Inc., Chicago, IL). Heart rate was monitored from a chest strap monitor (Polar 810i, Lake Success, NY).

The metabolic rates represent the highest 1-min average (VO_2) during each of the 3-min walking stages. Metabolic rate was defined as mL of oxygen consumed per kg of the subject's body mass, per minute (mL•kg^{-1}•min^{-1}). For all metabolic data, the best second order polynomial fit was used for displaying trend lines.

Due to the limited sample size ($n = 6$), inferential statistics were not used; therefore, statistical significance was not calculated. For these analyses a change in metabolic rate of 3.5 mL•kg^{-1}•min^{-1} was chosen for practical significance. Rationale for this choice was described in the IST-1 final report (1).

3.6 Biomechanical Collection and Analysis

Four strain-gauge type force plates (AMTI, Watertown, MA) were mounted to the frame of the treadmill under the belt and recorded ground reaction force (GRF) during the ambulation trials. The GRF recorded on the treadmill were normal (perpendicular) to the surface of the treadmill. Two additional force plates (AMTI, Watertown, MA) were used during the exploration task trials to record GRF and center of pressure (COP). During the exploration tasks, the subjects would stand on top of the force plates while performing their task.

A state-of-the-art Vicon MX motion capture system (Vicon, Oxford, England) was used to capture the kinematic data. Small retro-reflective markers were placed on key landmarks of the body and on the CG rig and gimbal. Data was processed with custom-made models for use with the CG rig and gimbal. This new model provided additional flexibility and accuracy over previous models. The model used inverse kinematics and dynamics to calculate the output variables. The data processed with these models output kinematic, kinetic, and temporal-spatial information. For this report we have used definitions, reference frames, and reference planes commonly used in the biomechanics and prescribed by the International Society of Biomechanics (7). Appendix A contains reference materials and graphical representation of the previously mentioned items.

The marker set used during the IST-3 testing was an unsuited marker set modified to be compatible with the CG Rig harness (see Figure 3–10). Six of the markers, shown in orange in the figure, were only used for a pretrial static data capture and were removed before the trials began. Ten additional markers were used on the CG rig and gimbal support structure to capture the motion data and location of the different rigid body sections (see Figure 3–11).
Figure 3-10. An illustration of the marker placements for the unsuited subject. The markers in orange were only used for a static recording and were removed before the trial began.
Figure 3-11. An illustration of the marker placements for the gimbal support structure and CG Rig.

Electromyography (EMG) was collected with a Telemyo 2400 (Noraxon Inc., Scottsdale, AZ, USA) wireless data collection system. The EMG signal was transmitted to the Vicon Nexus software and was recorded with the other data at a 1000 Hz sampling rate. Processing of the data was done using custom code written with MATLAB software. The EMG sampling sites were rectus abdominis, erector spinae, rectus femoris, vastus lateralis, semitendinosus, anterior tibialis, and soleus muscles.

Before testing, subjects were prepped for electrode application. This included shaving the hair, removing dead skin cells, and using an alcohol swab to remove excess dirt for each application site. The surface electrodes were silver-silver chloride dual snap electrodes with a diameter of 1 cm each (Noraxon Dual Electrode). Each surface electrode was applied and secured with co-band. The subjects then wore spandex pants with the cables coming out at the waist for testing. The CG rig harness was placed on the subject in a manner that would not apply pressure or tension to the EMG electrodes or cables. All EMG electrodes were applied to the right side and only the right foot was used for event markers.

All raw data were filtered with appropriate filtering algorithms. Because of the data collection frequency differences, the 1000 Hz data was either down-sampled to 100 Hz or expressed as time independent variables.

3.7 Subjective Data Collection and Analysis

The following subjective ratings were recorded at various times throughout the test (Additional information on each of these scales is included in Appendix B.):

- Ratings of Perceived Exertion (RPE) (8) were used to gauge how much effort subjects felt they must exert to complete each condition. RPE was collected at 30 s into the trial and during the last 30 s of the ambulation trials. RPE was collected immediately upon completion of all postural stability and exploration tasks. With the small sample size, statistical significance was not tested,

but rather levels of practical significance have been predefined. For these analyses, a change in RPE of 2 was chosen for practical significance. RPE changes of one unit are approximately at the level of practical significance for VO_2, but because RPE is a whole number scale, it would take a change > 1 to see practically significant differences in metabolic rate.

- The Gravity Compensation and Performance Scale (GCPS) was used to determine the level of compensation a person feels is necessary to maintain performance as compared to their performance unsuited in 1-g (5). GCPS was collected at 30 s and during the last 30 s of the ambulation trials. GCPS was collected immediately upon completion of all postural stability and exploration tasks. GCPS is not a continuously linear scale like RPE. Therefore, changes in GCPS are more complicated to assign a simple level of practical significance. It is reasonable to define a range of GCPS where changes within the range are of interest but would not be considered to be practically significant. Using this breakdown, we selected a GCPS category of 1 to 3 as "ideal", 4 as "acceptable", 5 to 6 as "modifications warranted", 7 to 9 as "modifications required" and 10 was "unable to complete task". Therefore, a level of practical significance for GCPS is one in which the value changes to a different category.

- The Corlett & Bishop Body Part Discomfort Scale was used to characterize discomfort at different body locations (9). Discomfort ratings were collected during the last 30 s of ambulation trials and at the completion of the postural stability testing and completion of the exploration tasks series.

- Thermal comfort and preference were assessed for two reasons: to determine the thermal comfort of the subject and to determine whether any changes were necessary to improve the thermal comfort of the subject during testing. Thermal comfort was assessed using the Bedford scale (10). Thermal comfort and preference were collected during the last 30 s of ambulation trials and at the completion of the postural stability testing and completion of the exploration tasks series.

The addition of collecting GCPS and RPE at both the 30-s mark during ambulation and at the end was to begin to determine if and how these ratings change over the course of time spent doing a constant activity and to be able to compare to results with a concurrent study using similar protocols during parabolic flight. In addition, GCPS will be used in conjunction with RPE to develop predictive models for metabolic rate with the intent that these subjective factors can be used in other lunar analog environments, such as underwater analogs and parabolic flight where direct measures of metabolic rate are currently not possible. Discomfort and thermal comfort were both primarily used for test termination criteria as well as to provide feedback to the test team about test hardware, conditions, and length of trials. Discomfort and thermal data will not be presented or discussed in this report.

3.8 Postural Stability Data Collection and Analysis

The primary postural stability data for this experiment were obtained from ground reaction forces sensed by load cell transducers mounted in the support surface and sampled at 100 Hz. Subject weight was determined at each test condition by averaging the summed values of the normal force transducers over the entire 100-s SOT 1 trial. During each trial, instantaneous subject COP position was computed from analysis of the load distributions among the four normal force transducers at each sampling time. Instantaneous center-of-mass (COM) sway displacement in the sagittal plane (X_{cm}) was then estimated by low-pass filtering ($f_c = 0.85$ Hz) the antero-posterior (AP) component of the COP displacement data, and instantaneous COM sway velocity (V_{cm}) was estimated by digitally differentiating the sway displacement data. Peak-to-peak (p-p) displacements and velocities over each trial were obtained from these data series.

A dimensionless performance measure, the equilibrium (EQ) score, was computed using the first 20 s of data from each SOT trial for comparison with clinical norms. Assuming a single link inverted pendulum model having a longitudinal COM location proportional to the subject's height, instantaneous center-of-mass sway angles, θ, were estimated from instantaneous X_{cm} data. The AP peak-to-peak sway angle, θ_{pp} (in degrees), was then used to compute EQ = $100 \times (1 - (\theta_{pp}/12.5°))$, where 12.5° is the theoretical maximum stable peak-to-peak sway displacement in the sagittal plane. Norms used for comparison in this study were obtained from the distribution of preflight performance scores obtained from more than 150 subjects previously tested in the JSC Neurosciences Laboratories.

More robust indicators of postural stability control were obtained by combining X_{cm} and V_{cm} data. Instantaneous time-to-contact (TTC) was defined as the amount of time it would take to reach the closest limit of stability (ie, fall) at any point in time during the trial. TTC was estimated throughout each trial by projecting the COM displacement from its current instantaneous AP position at its current instantaneous AP velocity until it intersected the limit of support represented by the maximum anterior or posterior aspect of the foot. The absolute minimum value of this data series over the trial, TTC_{min}, was used as an estimate of the greatest threat to postural stability during each trial. When loss of balance occurred, TTC_{min} was 0 s. An estimate of the average value of the threat to postural stability was obtained by numerically integrating the instantaneous TTC curve beneath an arbitrary ceiling set at TTC=10 sec. This parameter, integrated time-to-contact (iTTC), indicated the amount of time during the trial that the TTC was ≤10 s. Thus, lower TTC_{min} values and higher integrated TTC (iTTC) values indicate decreased performance. For the 100-s duration SOT trials, the minimum and maximum possible values for the iTTC were 0 s^2 and 1000 s^2, respectively, while for the 10-s duration MCT trials, the minimum and maximum possible values were 0 s^2 and 90 s^2 (analysis was limited to the 9-s recovery period that followed the perturbation).

3.9   Imaging

Digital video was taken for each subject during every test condition. Audio was not captured consistently during the video recording. Whenever possible, digital photographs were taken of the subject from the front and side during each test condition.

4   Results and Discussion

4.1   Center of Gravity Locations

Center of gravity locations for the system CG in relation to the subject and the gimbal axes of rotation were modeled before the test to provide the configuration of the CG rig for each condition, but these locations were based on the standard subject model (182.9 cm, 81.6 kg). To determine how much variation occurred because of varied subject anthropometry, further analysis was performed using each individual subject's height and weight to modify the standard subject model upon completion of the test sessions. Subjects were lined up in a consistent orientation (top of the shoulder lined up with the top of the back plate) to the gimbal support structure and then the CG of the system and the relation of the system CG to the gimbal axes of rotation were recalculated. This recalculation proved valuable for another reason. Three of four CGs were well tolerated, but the CTSD CG was consistently the most difficult for all subjects to cope with. When performing tasks in this CG, many subjects described the feeling as similar to a "horse-collar" tackle in football (11) (12), with subjects feeling as though they were being pulled down and backwards from the base of the neck. Because subjects did not experience this

with any of the other conditionsthe investigative team believed that there was an error in the initial model calculations.

Figure 4-1 demonstrates the variability in how the system CG varied from the subject CG on an individual basis and with reference to the initial model calculations. In most cases, the system CG locations with respect to the individual subject CG were within 2 cm in any direction of the model calculations. For the Perfect and Backpack CGs, the variation was primarily in the y-axis, but for the CTSD and POGO CGs, the variation was in both the x- and y-axis.
Figure 4-1. Individual subject differences in how the system CG varied from the subject CG.

Figure 4-2 shows the relationship of the system CG to the gimbal axes of rotation. Again, the variation in the Perfect and Backpack CGs are primarily in the y-axis and the CTSD and POGO variation was in both the x- and y-axis. In previous studies, when subjects were allowed to freely choose how they are oriented into the gimbal, the system CG was typically aligned so that it was slightly (≤ 2.5 cm) forward and low of the gimbal axes of rotation (5) (1). This positioning is assumed to be the most advantageous to human performance. Given the orientation of the human body and the types of tasks performed in this test, we expected that small variations in the y-axis alone would not account for significant physiologic changes during upright type tasks because the variation would still be in line with the lift vector and gravity. On the other hand, variations in the x-axis could impact performance, especially during upright tasks, as the POGO and gimbal system would impart rotational forces to line up the system CG with the lift and gravitational forces in the vertical plane. Of the four CG locations, only

the CTSD CG had an alignment that placed the system CG behind the gimbal axes of rotation, which would be consistent with the subjects' experience where they felt they were being pulled down and backward.
Figure 4-2. System CG relation to the gimbal axes of rotation for each individual subject.

4.2   Level Ambulation

Out of 180 trials, 174 were completed. All of the missing trials come from the CTSD CG condition. Half of the missing trials were not completed because the subject exceeded the maximum heart rate (HR), as described in Appendix F: Test Termination Criteria, during the prior trial. The other missing trials were not completed because of subject discomfort and an inability to position the subject properly in the rig.

4.2.1 Metabolic Results and Discussion

Metabolic rate was very similar for all varied CGs, except for CTSD, which had higher mean metabolic rates at all speeds (Figure 4-3). The baseline 1-g results were similar to the varied CG conditions while walking at speeds through 1.25 m•s^{-1}. Baseline 1-g results were slightly greater than all but CTSD at 1.67 m•s^{-1}, and were significantly (> 3.5 mL•min^{-1}•kg^{-1}) greater during the running speeds than all other CG conditions.
Figure 4-3. Metabolic rate for different CG conditions during shirt-sleeved ambulation on a level treadmill.

Figure 4-4 shows the nearly complete overlap of metabolic rate for the Perfect, Backpack, and POGO CG conditions, with the CTSD CG trending significantly higher on average. All of these were unexpected findings. Preliminary predictions were that the Perfect and Backpack CGs would lead to similar performance, because they were closest to the 0,0 origin and that the CTSD and POGO CGs would lead to similar performance, because they were both high and aft locations. To have the less high and aft (CTSD) of the two high and aft CGs (CTSD and POGO) lead to significantly higher metabolic rates was not expected. Reasons for this poor performance were more likely related to the misalignment of the system CG with the gimbal axes of rotation than to the actual offset of the system CG from the subject's CG. Finally, all but the baseline 1-g data showed linear trends relating metabolic rate to speed.
Figure 4-4. Metabolic rate for different CG conditions during shirt-sleeved ambulation on a level treadmill.

Figure 4-5 shows similar metabolic responses for all subjects while walking and running on a level treadmill in 1-g and in simulated lunar gravity at the different CG configurations. For the varied CG conditions, individual differences were not clearly evident for any CG other than the CTSD CG, with several subjects failing to complete all 6 speeds. Subjects were able to complete all trials at all other CG configurations.
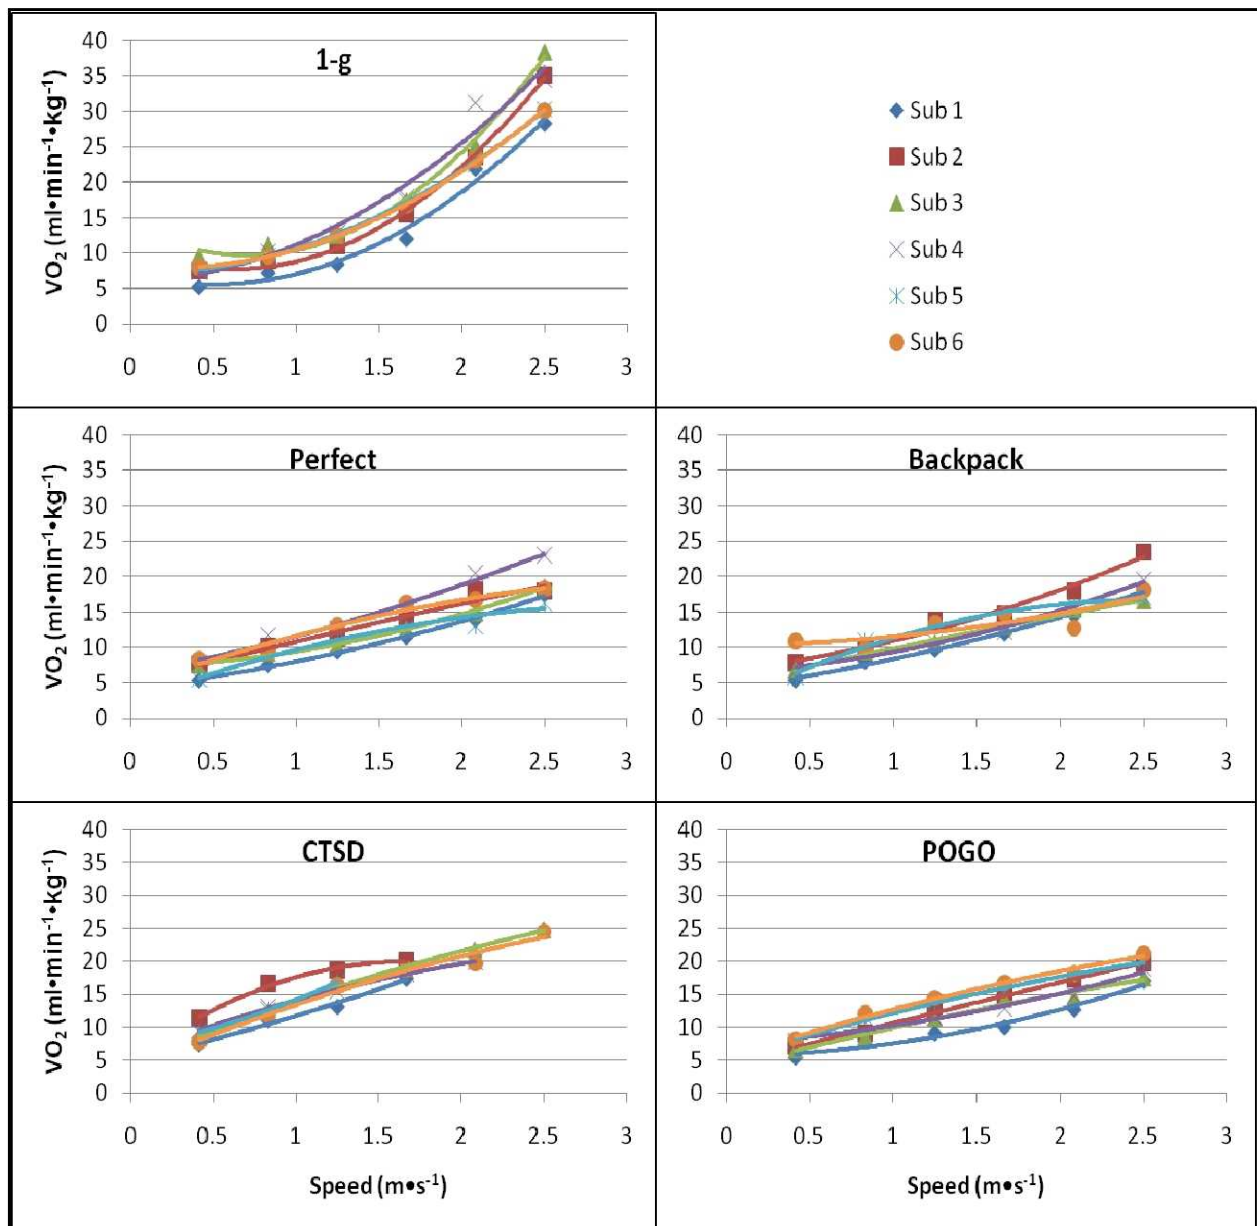

Figure 4-5. Individual metabolic rate responses to increasing speed on a level treadmill in 1-g and for different CG conditions during shirt-sleeved ambulation on a level treadmill at 1/6-g.

4.2.2 Biomechanics Results and Discussion

4.2.2.1 Kinetics

Kinetic analysis describes the methods the body uses for energy storage, absorption, transfer, and expenditure. Studying these interactions, one can determine the nature of the interactions between the human body and its environment. Normally, the body is a self-sustaining dynamic entity that receives no energy inputs from the surrounding environment. The POGO testing environment is not a passive

environment and will impart some energy into the human body during ambulation. For this test, kinetics were measured via the GRF for the six crewmembers for all conditions completed.

In the current test, as with previous tests in the IST series, kinetic data were provided in the form of peak vertical GRF that represents the normal force acting on the subject when they are in contact with the walking surface (treadmill). Typically, in literature as well as these studies, GRF is represented as a function of body weight (BW). In the current study, GRF values for all tested conditions were normalized to the subjects' 1-g BW. Normalization of the GRF data to subjects' respective BW allows for a direct comparison to be made across these subjects for the tested conditions.

4.2.2.1.1   *Ground Reaction Force*

In the current study, normalized peak vertical GRF for 1-g ambulation increased with an increase in ambulation speed (Figure 4-6). This follows expected trends seen in literature (13). As illustrated in Figure 4-6, a more notable increase is seen in normalized GRF values for the 1-g trials at 2.1 and 2.5 $m \bullet s^{-1}$ (ie, running trials). Conversely, normalized peak vertical GRF for all CG rig conditions appeared to plateau after subjects reached a 1.7 $m \bullet s^{-1}$ ambulation speed. This may indicate a less prominent change in adopted gait pattern at higher speeds, since the subjects were offloaded to lunar gravity and did not need to develop as much propulsive force during gait.

Literature shows that peak vertical GRF during 1-g running registers roughly 2.5 times BW (13) (14). Results from the 1-g condition followed this, with normalized peak vertical GRF values ranging roughly between 2.3 and 2.6 times 1-g BW for the 2.5 $m \bullet s^{-1}$ running trial (Figure 4-6). Data from offloaded conditions reveal that GRF experienced by subjects in the CG rig ranged from approximately 0.5 times BW at a speed of 0.4 $m \bullet s^{-1}$ to approximately 1 BW at 2.5 $m \bullet s^{-1}$. Minimal differences between varying CG conditions were observed for all subjects across all ambulation speeds (Figure 4-6).
Figure 4-6. Mean peak vertical ground reaction force (GRF), normalized to subjects' 1-g body weight, for shirt-sleeved ambulation on a level treadmill at different speeds. All varied CG conditions were performed at simulated lunar gravity.

4.2.2.1.2 CG Excursion in the POGO Test Environment

Moving the body's CG is one of the main modes the body has of energy absorption, transfer, and expenditure. During walking and running the body expels energy propelling its CG up and forward, then absorbs energy as the body comes back down and reacts with the ground (15). The faster a person walks or runs, the more energy is put into moving the CG. At first a person would suppose that minimizing the CG excursion would improve the overall efficiency of the system, but it has the just the opposite effect in reality (16) (17). This is in part due to the human body's leg bones acting as a type of pole vault to help redirect the CG vector with little muscle work.

Figure 4-7 and Figure 4-8 display the ranges of CG excursion per condition and per treadmill speed and the percentage difference between the unsuited 1-g condition and the CG rig conditions. The excursion was only examined in the vertical direction and at roughly the same point (pelvis centroid) on all subjects. Dots represent the average of each subject's average over all cycles for the left foot. Error bars represent the standard deviation of those averages across subjects. The unsuited 1-g condition followed a near linear progression from low to high speeds. The varied CG conditions followed a parabolic trend. The spread of the averages is fairly tight across the speed conditions. The middle speed of 1.3 $m \cdot s^{-1}$ also seemed to be a common point of excursion range between all conditions.
Figure 4-7. The average CG excursion range (pelvis centroid) between conditions with respect to speed.

36
Figure 4-8. The change in CG excursion range of the CG rig conditions compared to the unsuited 1-g condition with respect to speed.

Examining the difference in excursion between the body and the CG rig can help determine the dynamics occurring between the mechanical system (POGO, gimbal, CG rig) and the human. In Figure 4-9, the pelvis centroid is plotted against the motion of the CG rig in a single sample of series of gait cycles. The actual displacements are shifted by a static offset so that the two traces overlap. Excursions of the CG rig were larger than that of the body throughout trials. There are three separate problems shown in this graph. First, substantial displacement differences were seen between the peak and valley measurements for the subject and the CG rig. The variability of the difference between the CG rig and subject CG would imply that the CG rig has significant freedom to move independently of the subject's body. Secondly, this independence allowed the subject and CG rig to become out of sync spatially and temporally. These differences occurred constantly between the CG rig and body. Gait cycle averages also were not uniform in magnitude. The peaks and valleys are slightly out of phase from each other, with the body leading the CG rig by 5 to 10% of the gait cycle in this sample. This phenomenon comes from the large inertia of the gimbal and CG rig system coupled to the POGO, causing the whole system mass (POGO, gimbal, CG rig, human body) to oscillate on a larger, slower scale on top of the smaller, quicker oscillations of the subject (?) CG during the gait cycle (see Figure 4-10). The nonuniform shape to the pelvis centroid peaks showed that there were changes to the body dynamics near its peak excursion. This was most likely the result of dynamic collisions with the CG rig via the harness as a result of the phase difference.
Figure 4-9. Sample of the vertical motions of the pelvis, taken at its centroid, as compared to the vertical motion of the center of the CG rig. (NOTE: the CG rig data points are shifted vertically by a static offset for graphing purposes).
Figure 4-10. Plot of the CG rig (red) with a 6th order polynomial fit (black) showing the slower system oscillation during 36 seconds of ambulation.

4.2.2.1.3   Inertial Forces in the POGO Test Environment

Inertial forces are not often thought about as they do not exist until an object with mass begins to accelerate. The human body is constantly accelerating and decelerating during ambulation, even though that ambulation may be at a constant speed. Aside from the whole body CG accelerations, each body

part (except for the head), is usually in some kind of dynamic motion. Therefore, each segment mass requires a small force to get it moving and then to slow it down again.

When ambulating in an environment such as the POGO, the gimbal has a substantial added inertia, as does the CG rig. In total, the CG rig and gimbal more than double the body's normal mass and add over 15 times the upper body's normal rotational inertia. As the body translates and rotates, the added mass and inertia become quite substantial and require the body to compensate and change the normal dynamics to limit the additional energy needed. Table 4-1 shows the inertial parameters of the human male standing and the human male torso segment against those of the current POGO gimbal. The principal axes for all three systems are located at the relative center of gravity and are nearly co-axial to each other. The Ixx axis is anterior-posterior (frontal plane), the Iyy axis is medial-lateral (sagittal plane), the Izz axis is superior-inferior (transverse plane).

Table 4-1. Inertial comparison between an average human male standing, the human male torso segment only, and the POGO gimbal.

Moment of Inertia (kg·m^2)	Standing	Torso Only	POGO Gimbal
Ixx (AP, through CG)	13.40	1.62	0.03
Iyy (ML, through CG)	11.89	1.08	3.95
Izz (SI, through CG)	1.72	0.38	14.54

4.2.2.2 Temporal-Spatial Characteristics

Temporal-spatial characteristics pertain to a series of parameters that can be measured during ambulation that help to differentiate changes in gait strategy or compensation for changing conditions. Primarily, they include timing of specific characteristics of gait (eg, time between initial contacts) or the spatial distances where these characteristics occur (eg, linear distance between the feet at the initial contact).

4.2.2.2.1 Stance Time

Stance time refers to the amount of time during the gait cycle that the foot is in contact with the walking surface. In the current study, subjects exhibited a consistent decrease in mean stance time with increased ambulation speed (Figure 4-11). Additionally, the variability observed across conditions notably decreased with increased speed.
Figure 4-11. Mean stance time in seconds for shirt-sleeved ambulation on a level treadmill at different speeds. All varied CG conditions were performed at simulated lunar gravity.

Figure 4-12 illustrates the variation observed between the various CG conditions and the 1-g no rig condition. At an ambulation speed of 0.4 m•s^{-1}, a notable variation in stance time values was observed,

possibly because ambulating at such a slow speed elicited the adoption of inconsistent gait patterns by the subjects. The largest percentage difference for all CG conditions except for the "POGO CG" was observed at the 1.7 m•s⁻¹ speed (approximately -25 to -28% difference from 1-g) that may indicate inconsistent gait patterns adopted by subjects at this speed while attached to the CG rig and being offloaded to simulated lunar gravity. As seen in the GRF data, the stance time for the CG conditions plateaus at the faster speeds, whereas the 1-g stance time does not.
Figure 4-12. Percentage difference for stance time between varying CG conditions and the 1-g, no rig condition as a function of speed.

4.2.2.2.2 *Step Width*

Step width refers to the medial-lateral distance between the left and right foot during the support phase of the gait cycle (ie, the portion of the gait cycle in which the foot is in contact with the walking surface). This metric can be used to provide an indication of stability during gait, with wider step widths suggesting greater amounts of effort to maintain stability.

Mean-step width decreased modestly with increased ambulation speed (Figure 4-13). Mean-step width for the 1-g condition was consistently lower than mean-step width for the varying CG rig conditions with the exception of the 1.7 and 2.1 m•s⁻¹ speeds. These results suggest a greater amount of stability during ambulation under 1-g conditions.. This is also demonstrated by notable percentage differences between offloaded conditions and the 1-g condition (Figure 4-14).

The lowest mean-step width for all conditions occurred at the fastest ambulation speed (2.5 m•s⁻¹) that suggests an increased amount of stability during stance at this speed. This may be because the stance time at this speed is considerably lower than at slower ambulation speeds (Figure 4-13). Additionally, subjects were less prone to making minor adjustments during each step/stride to maintain posture and forward progression at the faster gait speeds than at the slower gait speeds.
Figure 4-13. Mean step width for shirt-sleeved ambulation on a level treadmill at different speeds. All varied CG conditions were performed at simulated lunar gravity.
Figure 4-14. Percentage difference in step width at different speeds between varying CG conditions at 1/6-g and the 1-g, no rig condition.

Mean-step width was examined using line plots to compare varying CG rig conditions to the 1-g, no-rig condition. Differences (Δ) were calculated using 3-dimensional trajectories of feet markers from motion capture data. It should be noted that differences exist between the following data and that

presented in earlier figures (see Figure 4-15). The reason for this involves the method used to determine and calculate step width. For instance, the following figures represent data that involves plotting of marker trajectory only. However, upon review of video footage, it was noted that several subjects adopted an off-balance gait when performing the ambulation tasks. Therefore, the results provided in the main body of the report reflect calculations that addressed this off-balance gait by accounting for the asymmetrical orientation of the pelvis. The Figure 4-15 plots, while calculated differently than preceding figures, still provide relevant data for examination of the effect of offloading and added mass on step width for an unsuited subject.

Subjects were unable to attain any consistent, cyclic motion in their gait pattern while ambulating at $0.4 \text{ m} \bullet \text{s}^{-1}$ that led to greater variability in step width. In fact, the 1-g, no-rig condition appeared to have a wider step width at this speed than any other speed (Figure 4-15), suggesting difficulty in maintaining consistency of gait at this speed.

For all gait speeds other than the slowest ($0.4 \text{ m} \bullet \text{s}^{-1}$) and fastest ($2.5 \text{ m} \bullet \text{s}^{-1}$), the lowest Δ from the 1-g no rig condition was observed for the "CTSD" condition. For both running speeds (2.1 and $2.5 \text{ m} \bullet \text{s}^{-1}$), the "POGO" condition was associated with the greatest Δ from the 1-g condition. This finding suggests that when ambulating at speeds requiring clear single-leg support and a greater swing phase of gait (i.e. running), the "POGO" condition was detrimental to unsuited performance. One explanation for this may be that subjects needed greater effort to maintain an appropriate posture due to the additional inertia of the apparatus in that configuration. As such they may have compensated via wider step width to maintain stability while ambulating at these higher speeds.
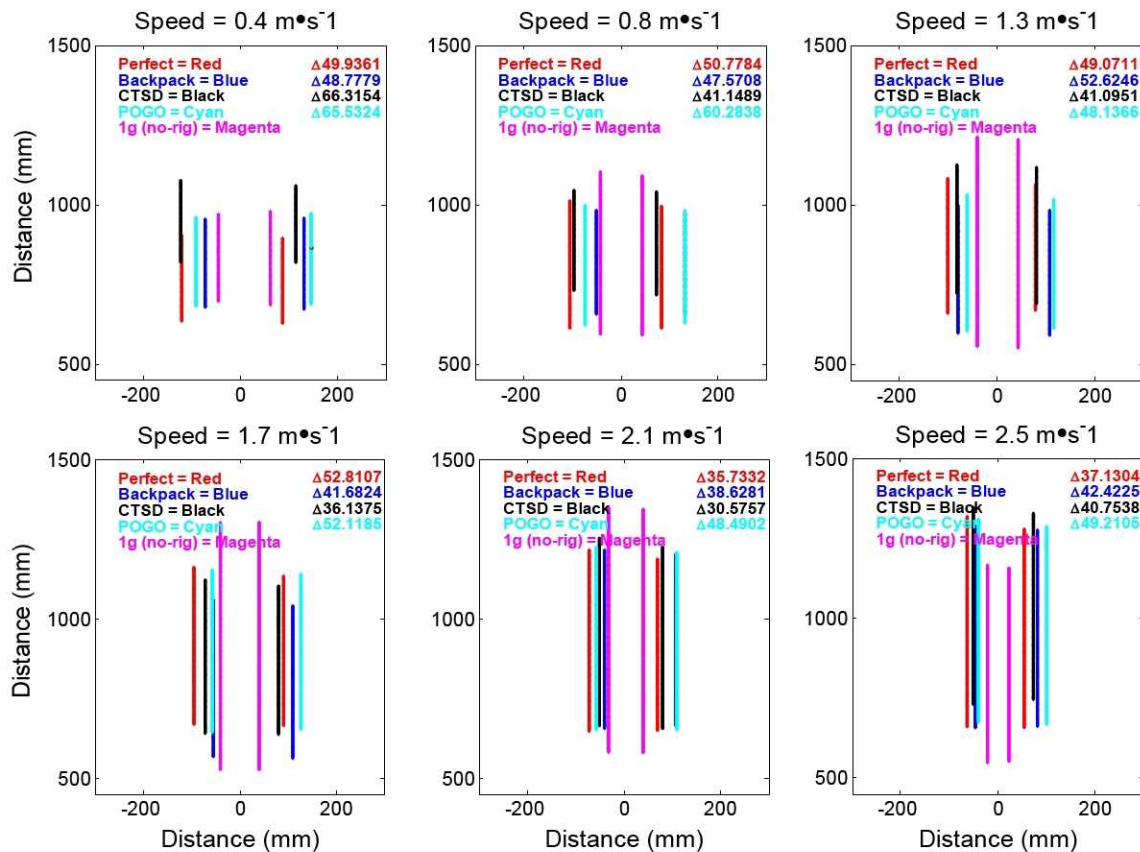

Figure 4-15. Change in step width between varying CG conditions and the 1-g, no rig condition for tested ambulation speeds.

4.2.2.3 Kinematics

For the review of kinematic data, first it is important to define some of the terminology used to describe the joint kinematics in the following discussion. The term flexion describes a decrease in relative angles between segments, and extension is an increase in relative angles between segments (Appendix A). Flexion will always be referred to as a positive angle, extension as a negative angle. This is not to be confused with an isolated joint ROM. For example, an isolated hip flexion has a clear defined starting and stopping point, namely the thigh segment moves from a neutral position of 0° and achieves some value of "X" and returns to the neutral position of 0° (Figure A-4). However, during gait the subject may never achieve a neutral position, given the dynamic nature of the movement. More specifically, gait is not a series of isolated movements; numerous concurrent actions are taking place during walking. Therefore, the accepted method of reporting joint angles is in terms of increases in relative angles between segments (extension) or decreases in relative angles between segments (flexion), or as total motion of the joint, expressed as a ROM. To be consistent with previous tests the generic term *initial contact* will be used to describe the instant when the foot just touches the floor, conversely, at the end of the floor contact the generic term *end contact* will be used.

Joint angles typically tell a story of how the human body is adapting to internal and external conditions to make smooth ambulation possible. Deviations from normal gait are observed and analyzed as to their magnitudes, timing, and curve shape among many others. During IST-3, joint angle ROM for the ankle, knee, hip, and torso in the sagittal plane of motion was recorded (see Figure 4-16 and Figure 4-17). Notice in the figures that there was little consistency between 1-g gait and gait while in the CG rig.

44

The one exception to this was at the highest speed for the ankle and hip ROM. Also, it was noted by analysis that the preferred method of ambulation while in the POGO was loping or hopping. This deviance changed for the ankle and hip angles at the fastest speed for all conditions as the subjects changed from a walk to run in the 1-g condition. The knee and torso angles still retained their deviance. The difference in the knee angles was due to the knee not having to flex as much to allow for toe clearance during the swing phase while hopping in the POGO. The torso angle difference was due to the restriction in movement by the POGO system and therefore could not adapt properly to changing conditions. Figure 4-18 shows the changes in ROM with respect to 1-g ambulation. Most noteworthy in this graph was the fact that the difference in the torso angles remained high throughout all conditions and speeds, as a result of the inability of the subjects to lean during ambulation. Difference in knee angles also remained high as the lofting motion of the lope reduced the need for the knee to flex to create adequate toe clearance.
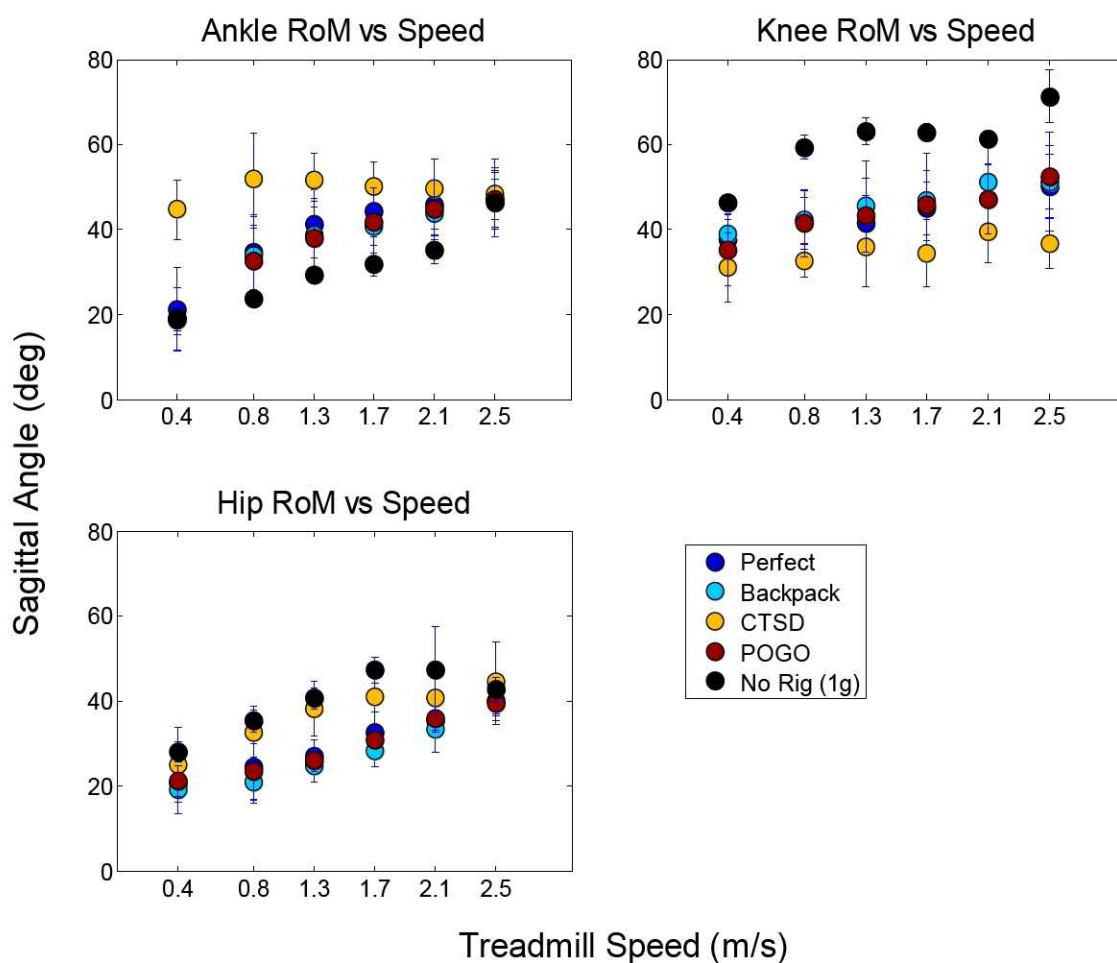

Figure 4-16. Joint angles averaged over subjects and gait cycles, categorized by CG condition, and plotted against speed. Error bars represent the standard deviation of the subject averages.
Figure 4-17. Torso joint angles averaged over subjects and gait cycles, categorized by CG condition, and plotted against speed. Error bars represent the standard deviation of the subject averages.
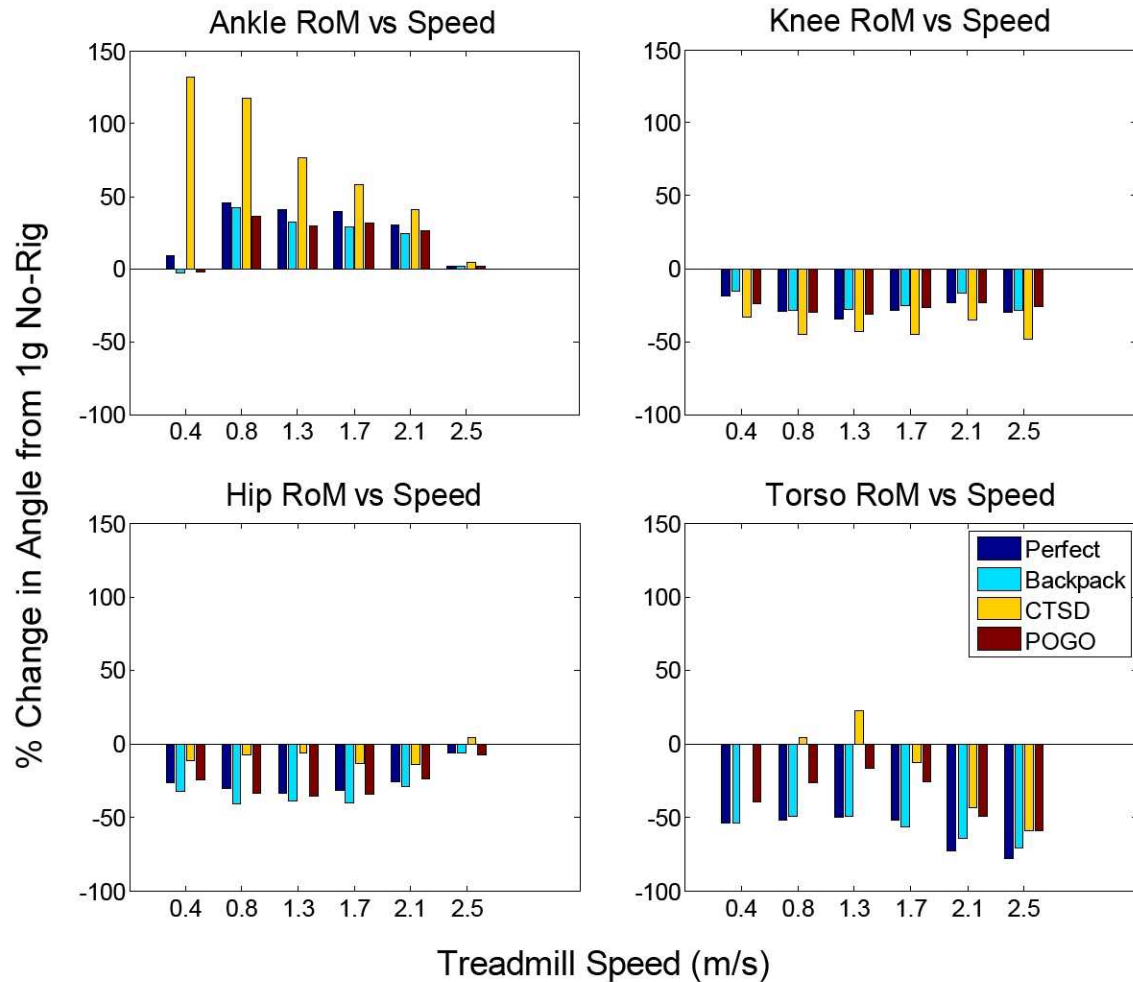

Figure 4-18. Percentage change in ROM of each CG condition from the unsuited 1-g baseline plotted against speed.

The next several graphs show the average angles for specific joints over the gait cycle, separated by treadmill speed (see Figure 4-19 to Figure 4-22). Most noticeably in all the figures, one will see the distinct differences in patterns between unsuited Earth-gravity ambulation and ambulation on the POGO. These patterns differed by shape, magnitudes, and timing of the maximum flexion and extension. Interestingly, there was little change between the different CG conditions over the range of speeds and only slight changes between the conditions themselves. This was markedly different from the unsuited condition, which had distinct changes in patterns and timing as the speeds progressed, especially at the highest speed (2.5 m•s^{-1}) when the subjects changed from a walk to run.

For the ankle angle (see Figure 4-19), the shape of the CG rig traces across all speeds were very similar in shape to the 2.5 m•s^{-1} unsuited 1-g trace. This shape was primarily due to abrupt loading at the heel immediately followed by peak plantar flexing for end contact. Similarly, the timing patterns of the peak plantar flexion angle changed with speed in an unsuited, 1-g environment between a walk and run. The timing of the unsuited 1-g trace at 2.5 m•s^{-1} was typical for running as the percentage of the gait cycle in contact with the floor decreases, allowing for a longer stride and greater speed.

47
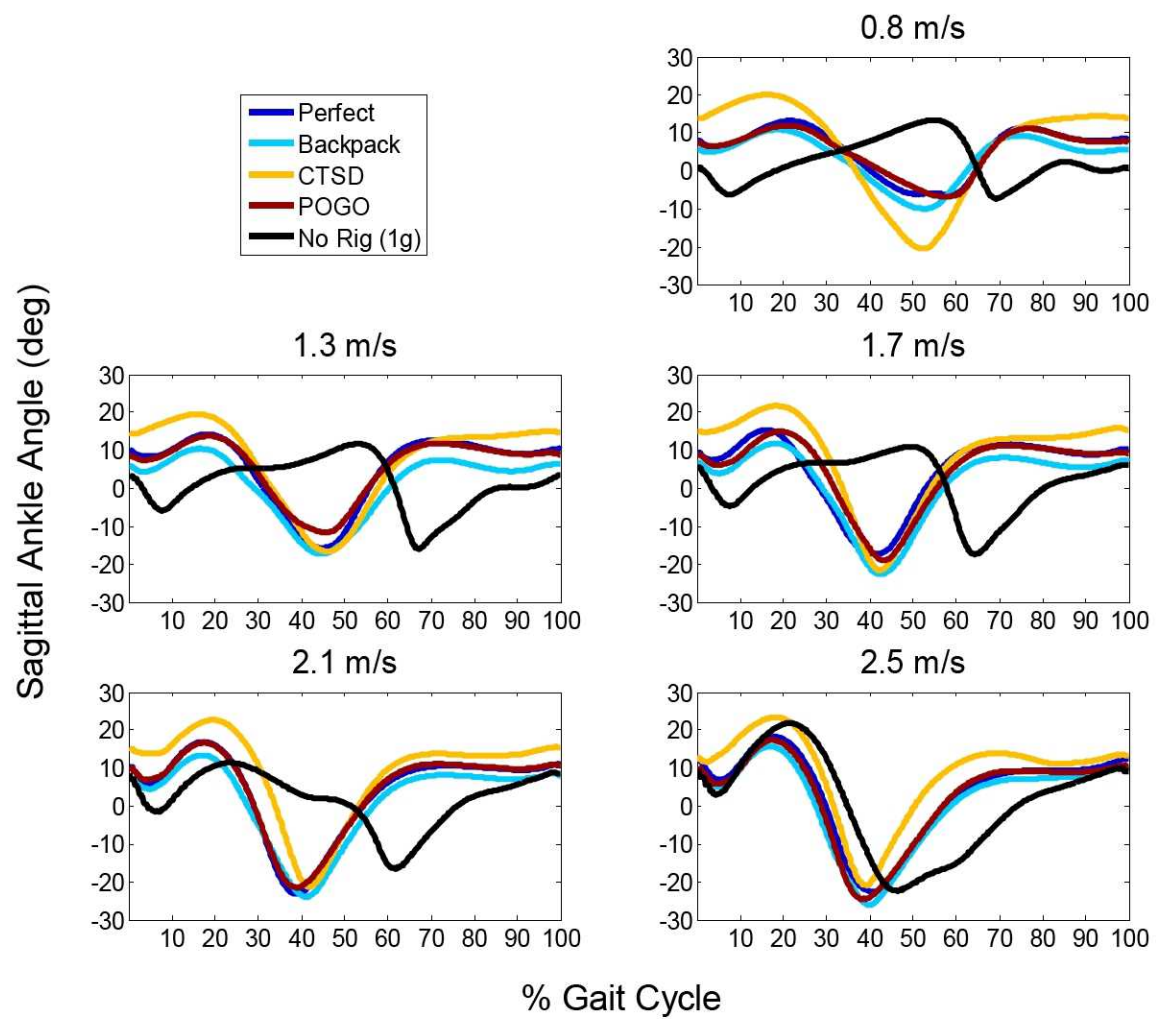

Figure 4-19. Ankle joint angle traces over one gait cycle for each CG condition. Each plot is at specific speed.
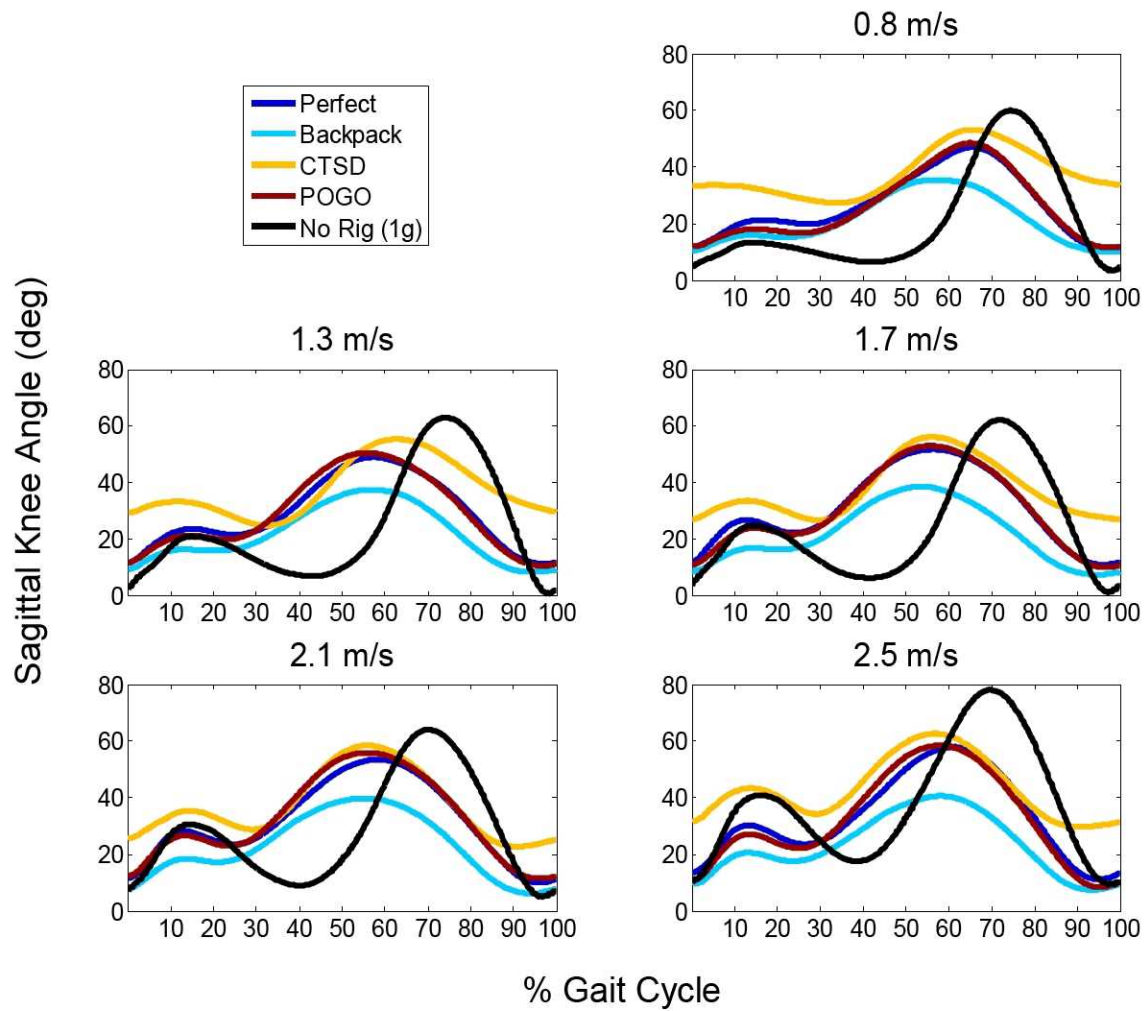

Figure 4-20. Knee joint angle traces over one gait cycle for each CG condition. Each plot is at specific speed.
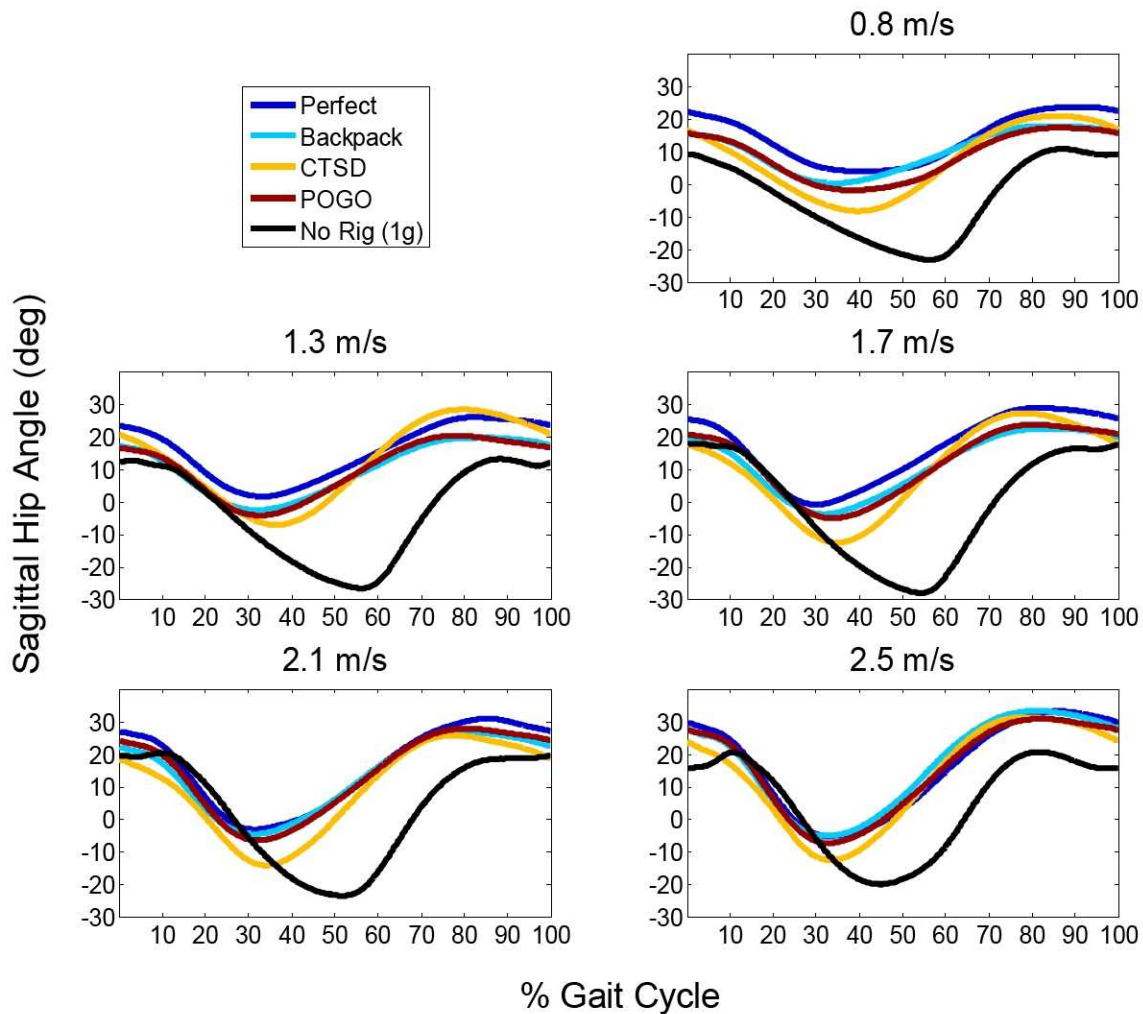

Figure 4-21. Hip joint angle traces over one gait cycle for each CG condition. Each plot is at specific speed.

For the torso angle (Figure 4-22), the shapes of the CG rig traces were fairly uniform in magnitude and amplitude as speed increased compared to the unsuited 1-g condition. For the unsuited 1-g condition, the angle decreased and then increased as the body used a strategy of transferring forward momentum from initial contact to end contact. As speed increased, this shifting became more pronounced. As the stance phase of gait cycle shortened with speed, the tilting adjusted equally. The exception to this was again the CTSD condition where the subjects tilted back as the speed increased. In the other conditions subjects remained at a constant forward tilt throughout the speed conditions.
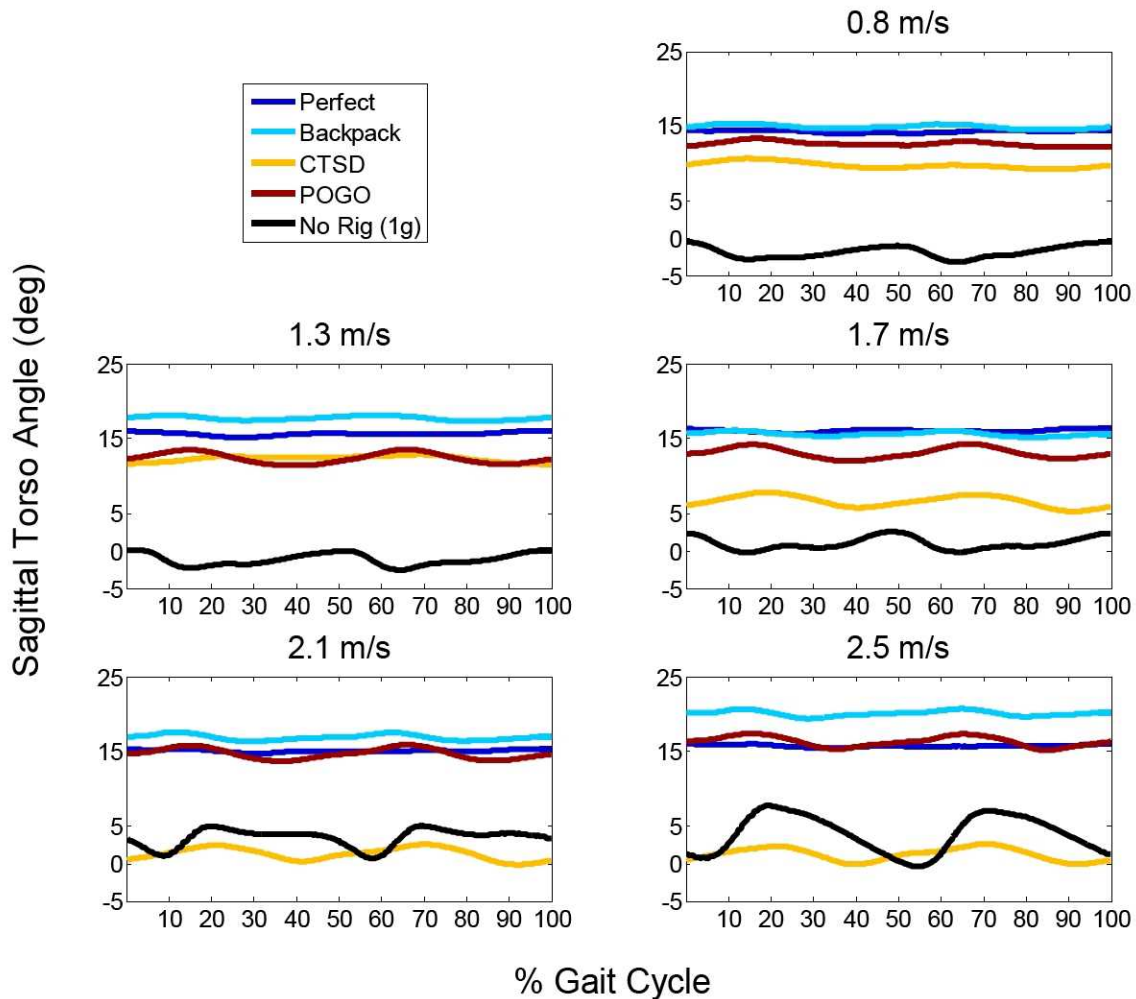

Figure 4-22. Torso angle traces over one gait cycle for each CG condition. Each plot is at specific speed.

4.2.2.3.1 *Offloading Mechanics*

This section will take a more in-depth look at how the POGO and gimbal/CG rig systems are interacting with the human subject. This comparison will primarily be done in the sagittal plane.

Changes to traditional heel strike and toe-off patterns were not always observed during the CG rig trials. Figure 4-23 shows the difference in lower limb kinematics at end contact when unsuited (left) and in the CG rig (right). In the CG rig trial, the stance phase of the gait cycle and the contact angle of the leg have been shortened so the leg can no longer produce as much propulsive force in the forward direction. Figure 4-24 shows the difference in lower limb kinematics at initial contact when unsuited (left) and in the CG rig (right). In the CG rig trial, the stance phase of the gait cycle and the contact angle of the leg have been shortened so the leg no longer absorbs energy produced by the body's forward momentum. The reduction of the stance phase of gait and the reduction of leg angles over that contact period would indicate that the body no longer imparts as much energy into the ground for propulsive means. If the body was still imparting force into the ground to move the body CG, the mechanics of the system dictate that the body was using primarily vertical propulsive forces.
Figure 4-23. End contact shown unsuited (left) and on the POGO with a rig (right). Yellow lines indicate the angle of the leg with respect to vertical.
Figure 4-24. Initial contact shown unsuited (left) and on the POGO with a rig (right). Yellow lines indicate the angle of the leg with respect to vertical.

Figure 4-25 shows how the body had to compensate differently for the CTSD CG. In this case, the subject shown has compensated by lowering the pelvis and putting the hip, knee, and ankle in more flexion at initial contact and more hip extension at end contact. This type of compensation is seen when a human is pulling or pushing objects.
Figure 4-25. Initial contact and end contact on the POGO at the CTSD condition. Yellow lines indicate the angle of the leg with respect to vertical.

4.2.2.4 Electromyography

The subject's maximum voluntary contractions (MVC) for the muscles were not recorded. Testing was done over a 2 to 3-day period. With the reapplication of electrodes days apart from the previous test day, the EMG signals were not comparable and; therefore, the MVC baselines would not be as useful. To compensate for this, a second method that applied a double-threshold detector to the raw EMG signal was used (18). However, an unforeseen complication was the heartbeat artifact in the rectus abdominis. High-pass filtering (19) was unsuccessful at removing the artifacts due to the artifact having a frequency in the middle of the range of the EMG frequencies.

Due to complications during testing, only two subjects had a full data set to analyze. Because of the complexity of the post data collection analysis due to the aforementioned problems incurred during testing, only the erector spinae of one subject was analyzed for this report and presented as an example.

The EMG results for the erector spinae at the level treadmill condition of 1.7 m•s^{-1} are presented in Figure 4-26. Shades of grey represent the instantaneous amplitude of the full-wave rectified signal. Three shades were chosen to show the level of activation based on the maximum of the rectified, smoothed signal. The darker shade signifies higher amplitude while a lighter shade was lower amplitude but still activation. The shade of gray is based on that trial only. Plots from all trials are included in Appendix E.
Figure 4-26. Erector spinae muscle activity during a gait cycle at 1.7 m•s^{-1}. The gray shading indicates the intensity of the contraction.

At this ambulation speed, toe-off occurred at approximately 35% of the gait cycle. The Perfect, Backpack, and POGO CG rig conditions were fairly similar with the right side erector spinae firing during the middle of the swing phase, which was also the middle of the stance of the left foot. The CTSD CG rig condition showed a longer period of activation. This longer period of activation would indicate more work was being done by these muscles for this condition over the others. There was a noticeable difference between each of the CG rig conditions and the 1-g unsuited condition. The 1-g unsuited condition had a burst of activity during initial contact and during the swing phase, which was normally seen (20).

4.2.3 Subjective Results and Discussion

All references to subjective data refer to the end of stage subjective ratings taken at the 3-min mark unless otherwise stated.

4.2.3.1 RPE

With the exception of 1-g data, RPE trends (Figure 4-27) were very similar to metabolic trends (Figure 4-3). Mean RPE for the CTSD condition was significantly greater than all other CG conditions

54

across all speeds, although the standard deviation range did have some notable overlap with the other CG conditions that was not present in the metabolic data. The 1-g RPE ratings seen at 2.1 and 2.5 m•s^{-1} were very similar to the values of the non CTSD CGs, which was not the case with the metabolic data. This indicates that subjects rated RPE differently under different conditions, such as freestanding in 1-g versus offloaded while connected to the gimbal support structure with CG rig. This is a similar finding to what was seen in previous studies where RPE was rated differently in the suited and unsuited conditions [5] [1] [2].
Figure 4-27. RPE at different CG conditions during shirt-sleeved ambulation on a level treadmill.

4.2.3.2 GCPS

GCPS ratings are shown in Figure 4-28. GCPS was significantly greater with the CTSD CG than with any other CG. Mean ratings at the CTSD CG indicated that modifications were warranted or required to attain desired performance. Ratings at all other CGs were similar and trended towards either desired performance or some modifications warranted to achieve desired performance. In addition, there was a subtle trend for GCPS to increase with speed, with the greatest increase coming at speeds ≥ 2.1 m•s^{-1}.

55
Figure 4-28. GCPS at different CG conditions during shirt-sleeved ambulation on a level treadmill.

4.2.3.3 Subjective Rating Changes from 30 s to 150 s

In previous ground based studies, RPE has been measured only near the end of steady-state tasks. Aside from a few exceptions, RPE was taken after 2+ min of steady state activity including level and graded ambulation, shoveling, rock transfer, and busy board tasks (5) (1) (2). GCPS has been used on both short and long tasks and was taken at the same time RPE was obtained or taken immediately upon completion of shorter tasks. In this study, RPE and GCPS were measured at both the 30-s and 150-s mark of the 180-s trials. Figure 4-29 shows the change in RPE and GCPS from the 30-s mark to the 150-s mark of the 180-s trials during level ambulation. In over 90% of the trials, the ratings either stayed the same (71% RPE, 82% GCPS) or increased by 1 (23% RPE, 12% GCPS).
Figure 4-29. Change in subjective ratings from the 30-s mark to 150-s mark in a 180-s level ambulation trial (*n* = 173).

4.3 Graded Ambulation

Out of 120 trials, 114 were completed. All of the missing trials come from the CTSD CG condition. Half of the missing trials were not completed because the subject exceeded the maximum heart rate (HR) as described Appendix F: Test Termination Criteria during the prior trial. The other half were not completed because of subject discomfort and positioning difficulty. An additional 30 trials from the level ambulation data set are included in the graded ambulation dataset because they provide the 0% incline data at 0.8 m•s^{-1}.

4.3.1 Metabolic Results and Discussion

Metabolic rate was very similar for all varied CGs, except for CTSD, which had significantly higher mean metabolic rates at all grades (Figure 4-30). With the exception of the aforementioned CTSD results, the baseline 1-g results were similar to the varied CG conditions at -10% and 0% grade. Baseline 1-g results were slightly greater than all but CTSD at 10%, and were significantly (>3.5 mL•min^{-1}•kg^{-1}) greater during 20 and 30% trials than all other CG conditions.
Figure 4-30. Metabolic rate for different CG conditions during shirt-sleeved ambulation on an inclined treadmill.

Figure 4-31 shows the nearly complete overlap of the Perfect, Backpack, and POGO CG conditions. CTSD trended significantly higher on average than all other CGs. Results were similar to the level treadmill data. Again, the higher metabolic rates in the CTSD condition were assumed to be explained by system CG misalignment with the gimbal axes of rotation. All but the baseline 1-g data showed linear trends relating metabolic rate to grade at a constant speed of 0.8 m•s^{-1} at simulated lunar gravity.
Figure 4-31. Metabolic rate for different CG conditions during shirt-sleeved ambulation on an inclined treadmill.

Figure 4-32 shows similar metabolic responses for all subjects during 1-g graded treadmill ambulation at 0.8 m•s^{-1}. For the varied CG conditions, individual differences were not clearly evident for any CG other than the CTSD (see Figure 4-32). Subjects were able to complete all trials at each condition other than the CTSD CG. The overall trends for individual subjects show a homogenous response to each CG condition with similar results and trends.
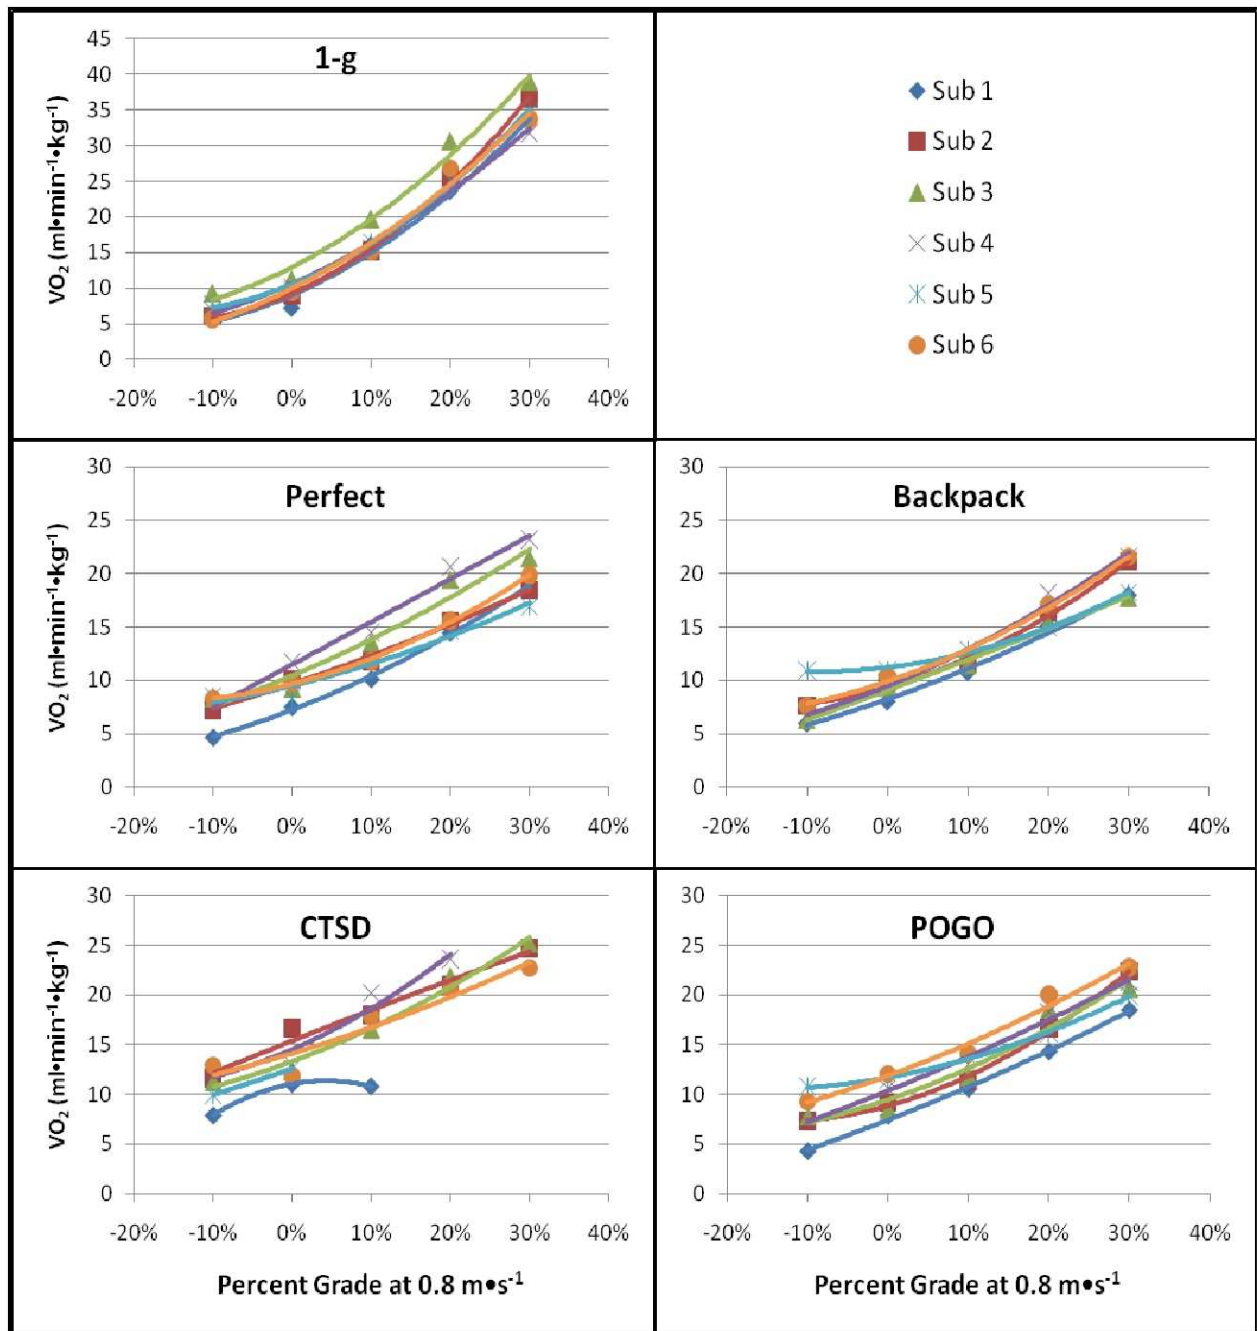

Figure 4-32. Individual metabolic rate responses to increasing grade on treadmill at 0.8 m•s⁻¹ in 1-g and at different CG configurations at simulated lunar gravity.

4.3.2 Biomechanics Results and Discussion

4.3.2.1 Kinetics

4.3.2.1.1 Ground Reaction Force

Peak normalized GRF data were analyzed for subject ambulation at varying treadmill surface grades, including -10%, 10, 20, and 30% incline (Figure 4-33). All of these trials were performed at an absolute ambulation speed of 0.8 m•s^{-1} (1.9 mph). In addition to comparison between varying surface grades, results were compared to level ambulation (ie, 0% incline) at the same absolute speed on the treadmill.

Results from the 1-g, no rig condition reveal a small variation in mean peak normalized vertical GRF across subjects between varying surface inclines and level ambulation (Figure 4-33). Though not markedly smaller than for other conditions, mean GRF values were lowest for level (0%) grade ambulation. This may be attributable to subjects' familiarity with level treadmill walking compared to walking at declined or inclined surface grades. The 10% decline condition yielded the largest peak normalized vertical GRF (mean approximately 1.4 times BW), although this was not a significant increase compared to level and incline ambulation. Additionally, the largest variation was observed during subject ambulation at the 10% decline, which may be attributed to the unfamiliar task of decline ambulation on a treadmill.

The variability of mean peak vertical GRF data across subjects for offloaded, varied CG conditions was notably greater than for the 1-g condition for all ambulation speeds (Figure 4-33). For the CTSD condition, mean peak vertical GRF tended to decrease with an increase in treadmill incline (approximately 0.7 BW at level (0%) walking to 0.5 BW at 30% incline), but a minimal change was observed in mean values between level and decline walking. Mean values for the CTSD CG condition exhibited a small but consistent decreasing trend in GRF with an increase in surface incline, but mean values for the other CG rig conditions did not reveal consistent trends across surface incline conditions.
Figure 4-33. Mean peak vertical ground reaction force (GRF), normalized to subjects' 1-g body weight for shirt-sleeved ambulation on a level treadmill (0%) and at surface grades of -10, 10, 20, and 30%. An ambulation speed of 0.85 m•s^{-1} was used across all varying surface grade conditions. All varied CG conditions were performed at simulated lunar gravity.

4.3.2.2 Temporal-Spatial Characteristics

4.3.2.2.1 *Stance Time*

Figure 4-34 illustrates mean stance time for ambulating at 0.8 m•s^{-1} at varying surface grades. The 1-g condition shows an increase in mean stance time across subjects with increased treadmill grade from the 10% decline to 20% incline. Mean stance time results for the various CG rig conditions do not appear to follow the same trends observed for the 1-g, no rig condition. For all CG rig conditions except "Perfect CG," an increase in stance time was seen from level treadmill to ambulation at the 10% surface decline. No clear trends were observed across CG rig conditions regarding mean stance time for ambulating at varying surface inclines. The POGO CG and Backpack CG conditions yielded an increase in mean stance time between level walking and 10% incline, but then exhibited a decrease in mean stance time as incline increased. The Perfect CG condition followed a similar pattern at these steeper inclines. The "CTSD CG" condition, however, showed a decreased stance time from level to 20% incline, with a slight increase in stance time between 20 and 30% incline (Figure 4-34). It should be noted that, except for the "POGO CG" condition at the -10% decline, mean stance times for all CG rig conditions were less than those for the 1-g, no rig condition across the tested surface grades.
Figure 4-34. Mean stance time for all subjects and conditions tested across surface grades of -10 decline, 0% (level), and 10, 20, and 30% treadmill incline.

As shown in Figure 4-35, mean stance time for all conditions except the "POGO CG" at the -10% decline is less than mean stance time for the 1-g no rig condition. At the steepest incline (30%), stance time for all CG rig conditions was less than stance time for 1-g ambulation at the same incline by greater than 25%.
Figure 4-35. Percentage difference for stance time between varying offloaded conditions and the 1-g, no rig condition across surface grades of -10 decline, 0 (level), and 10, 20, and 30% treadmill incline.

4.3.2.2.2   Step Width

Figure 4-36 shows minimal differences in mean-step width across varying surface grades for 1-g, no rig ambulation. All mean values for this condition corresponded to a step width of approximately 0.1 to 0.15 m. Mean step width values for all varying CGs were larger than values for the 1-g no rig condition. The largest deviation from the 1-g condition was observed at the -10% treadmill grade (approximately 120% greater than 1-g conditions), while the smallest deviation (approximately 5% greater than 1-g) was seen at the 20% treadmill grade for the POGO, Perfect, and Backpack (Figure 4-37). The percentage difference between the CTSD and the 1-g conditions increased between level walking and 20% grade conditions. No remarkable difference was observed in percentage difference from 1-g between 20 and 30% grades.
Figure 4-36. Mean step width (m) for all subjects and conditions tested across surface grades of -10 decline, 0 (level), and 10, 20, and 30% treadmill incline.
Figure 4-37. Percentage difference for step width between varying offloaded conditions and the 1-g, no rig condition across surface grades of -10 decline, 0 (level), and 10, 20, and 30% treadmill incline.

4.3.2.3 Kinematics

Walking on an incline compared to walking on the horizontal can be distinguished by the following factors: the requirements to raise or lower the body's center of mass, the vertical displacement during each stride, foot clearance, and joint ROM. The following paragraphs address these factors.

Numerous studies have demonstrated that the angle of incline is a factor influencing the hip, knee, and ankle angles (21). These studies concluded that the governing factor regarding the effect of incline on lower extremity joint angle may be the orientation of the center of mass of the upper body during these tasks. For this stage of IST-3, the joint angles were recorded for the ankle, knee, hip, and torso in the sagittal plane of motion while the treadmill was inclined or declined at different percentage grades. In Figure 4-38 and Figure 4-39, the joint ROMs are displayed with respect to the incline and the condition. As shown in the figures, the angles between unsuited gait and CG rig gait joint angle ROM are not very close, but the general change in ROM follows the same pattern. The decrease in knee and hip ROM and the increase in the ankle ROM indicate that the subject was not using the same kinematics to adapt to the changes in the environment. Figure 4-40 also shows a relatively consistent percentage difference between the unsuited 1-g condition and the CG rig conditions.
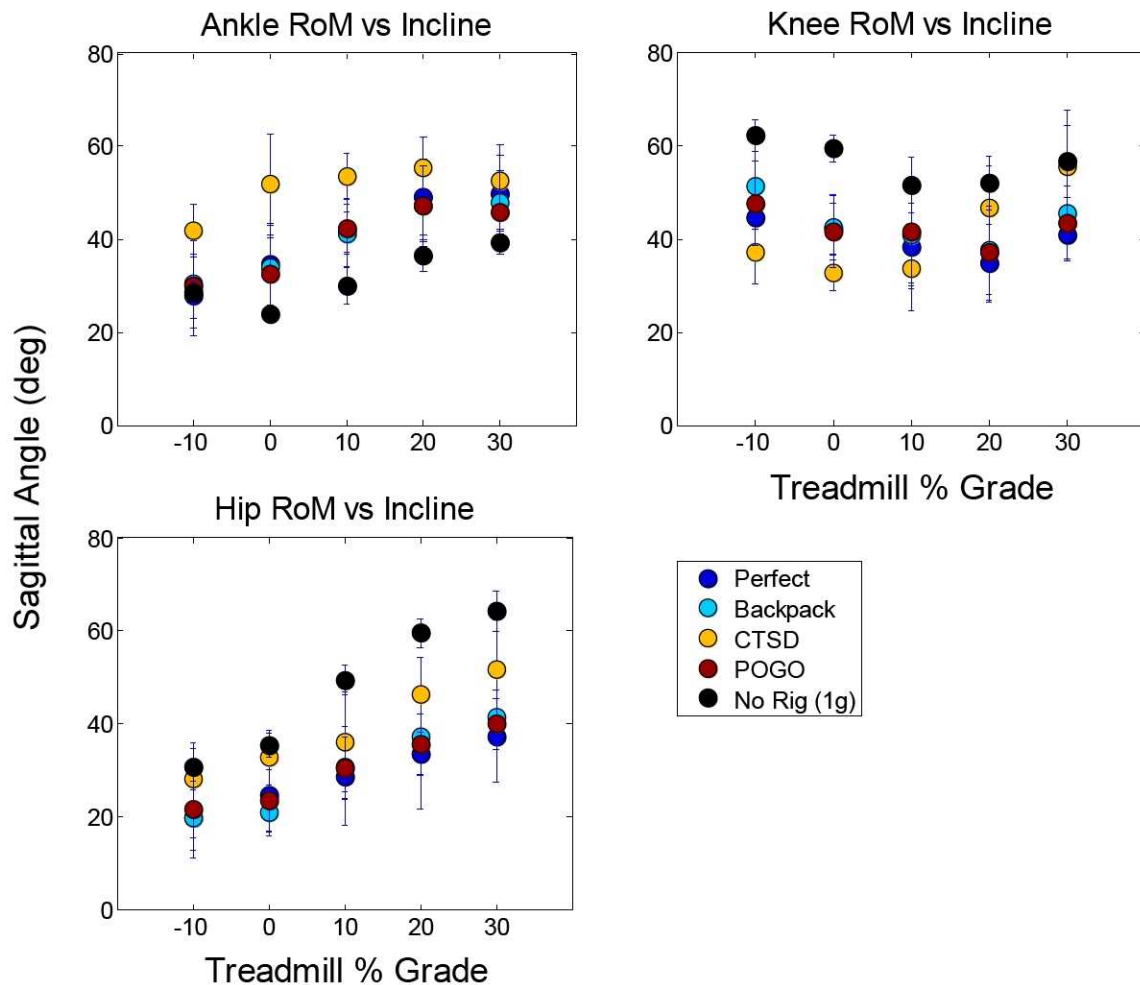

Figure 4-38. Joint angles averaged over subjects and gait cycles, categorized by CG condition, and plotted against incline. Error bars represent the standard deviation of the subject averages.

65
Figure 4-39. Joint angles averaged over subjects and gait cycles, categorized by CG condition, and plotted against incline. Error bars represent the standard deviation of the subject averages.
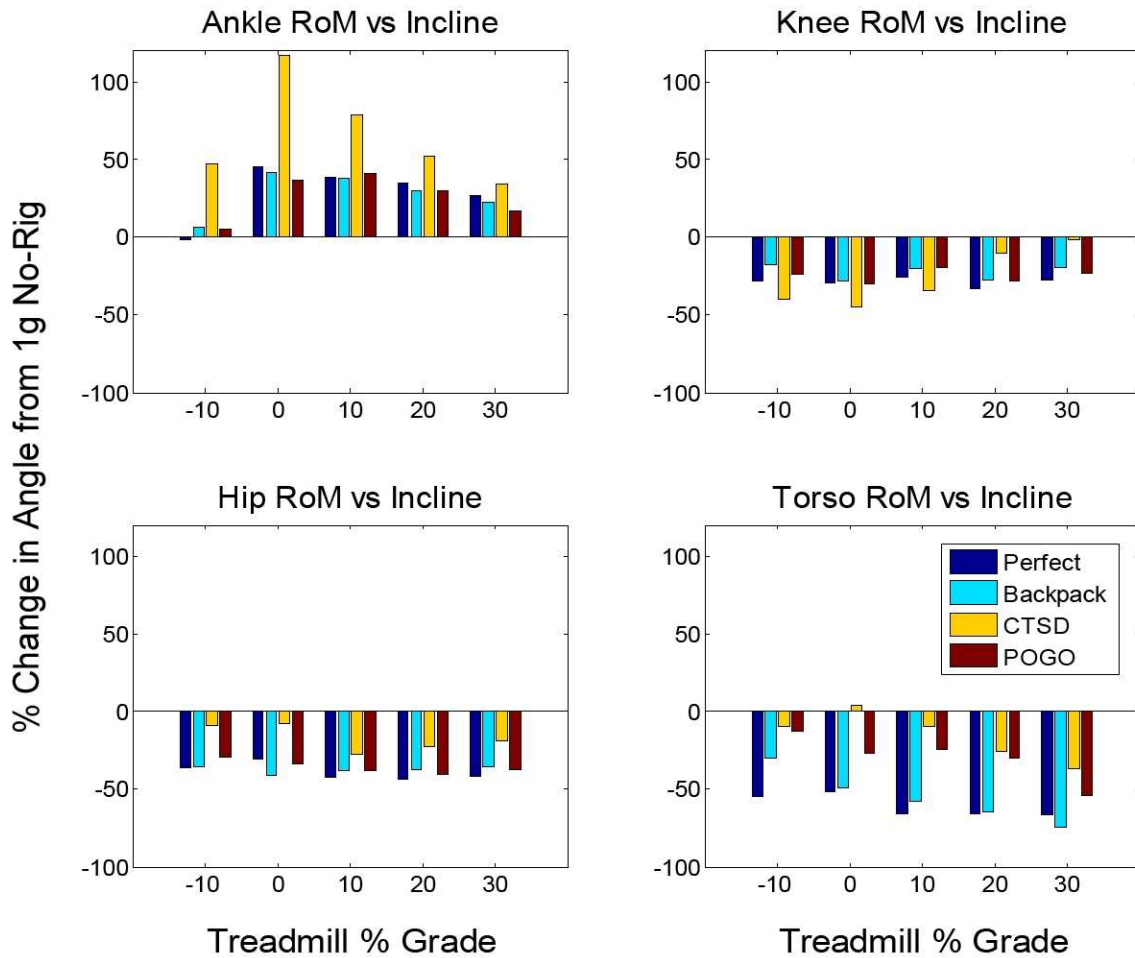

Figure 4-40. Percentage change in ROM of each CG condition from the unsuited 1-g baseline plotted against incline.

The next several graphs show the average angles for specific joints over the gait cycle, separated by treadmill incline (Figure 4-41 to Figure 4-44). Distinct differences in patterns are noticeable between unsuited Earth-gravity ambulation and POGO ambulation. These patterns differ by shape, magnitudes, and timing of the maximum flexion and extension. Again, there is little change between the different CG conditions over the range of inclines and only slight changes between the conditions themselves, the exception being the CTSD condition that displays a little more variability. The patterns are noticeably different from the unsuited condition, which has distinct changes in patterns, magnitudes, and timing as the inclines progress.
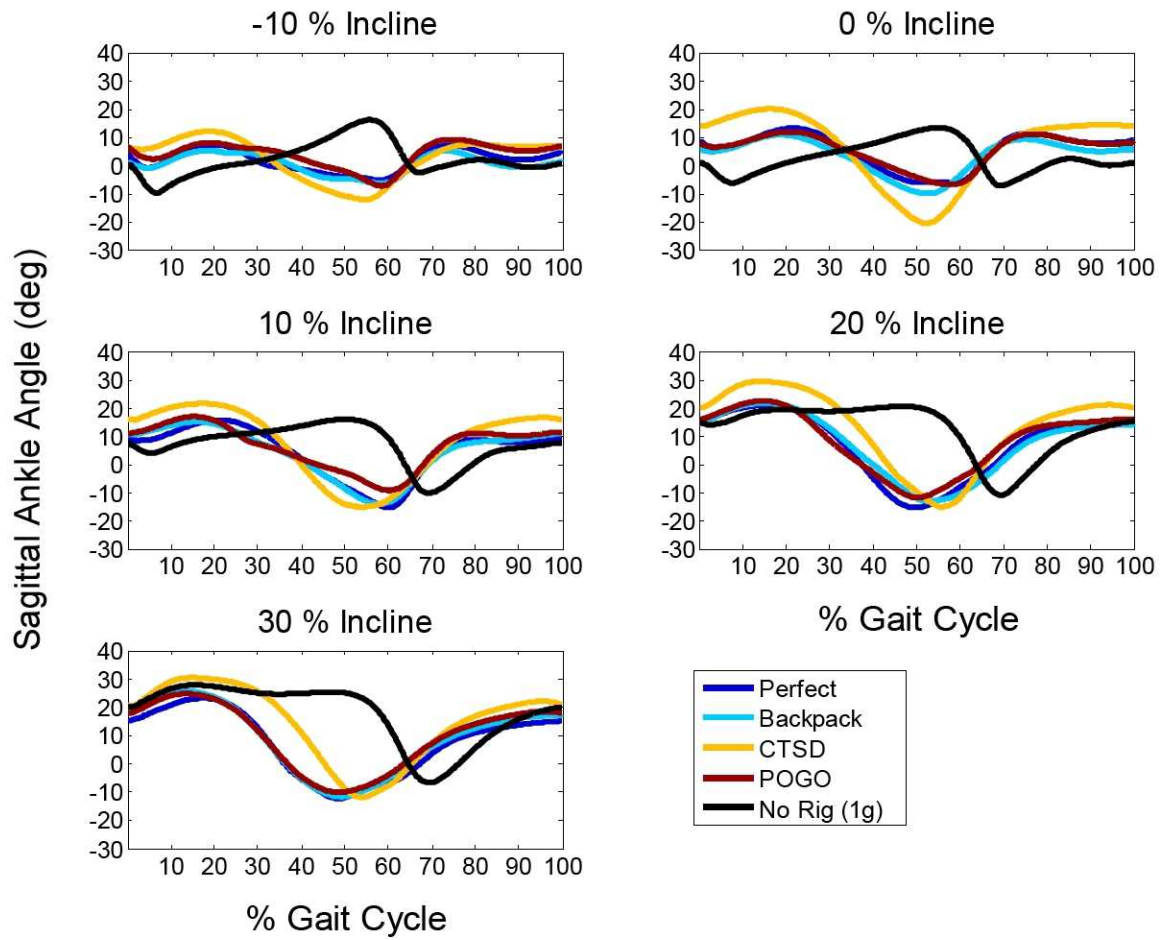

Figure 4-41. Ankle joint angle traces over one gait cycle for each CG condition. Each plot is at specific incline.
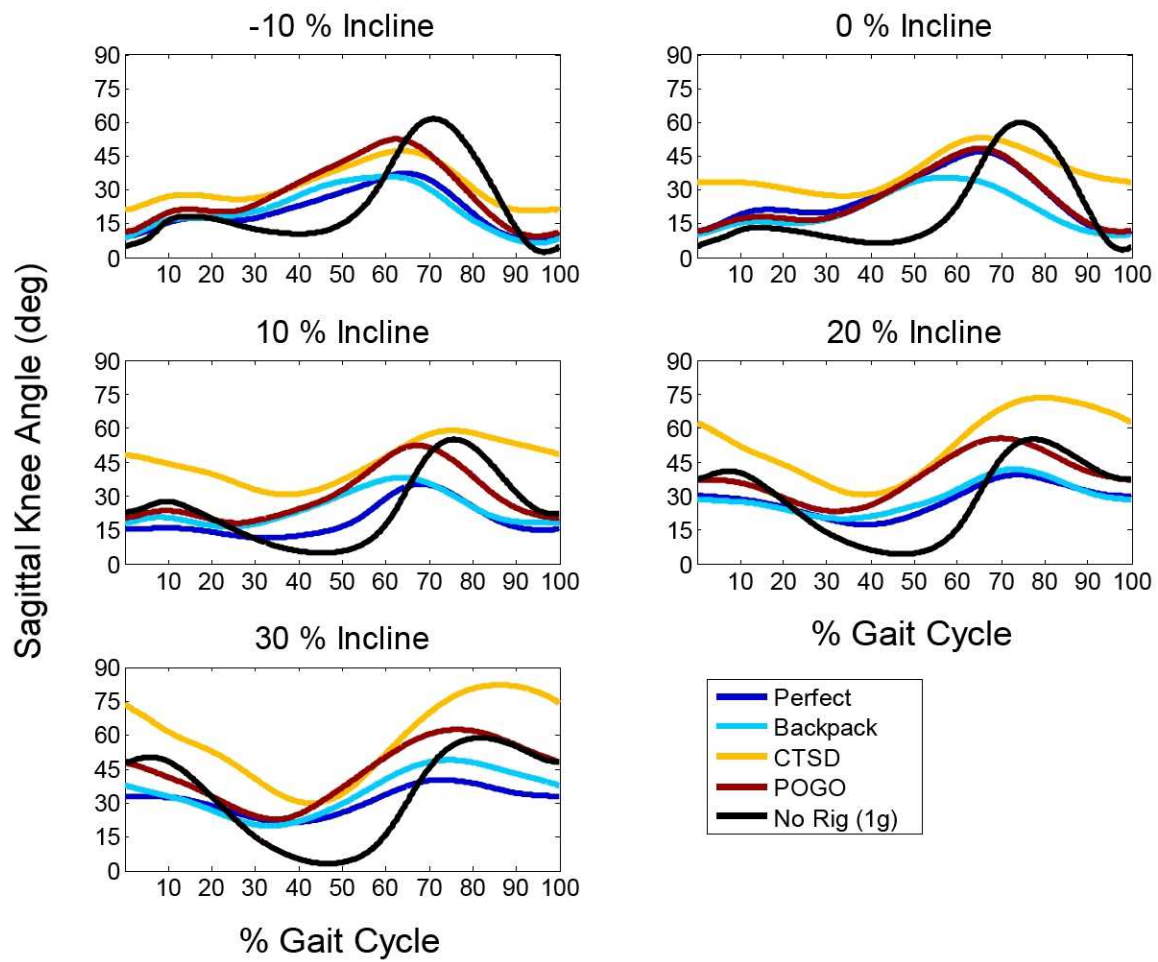

Figure 4-42. Knee joint angle traces over one gait cycle for each CG condition. Each plot is at specific incline.
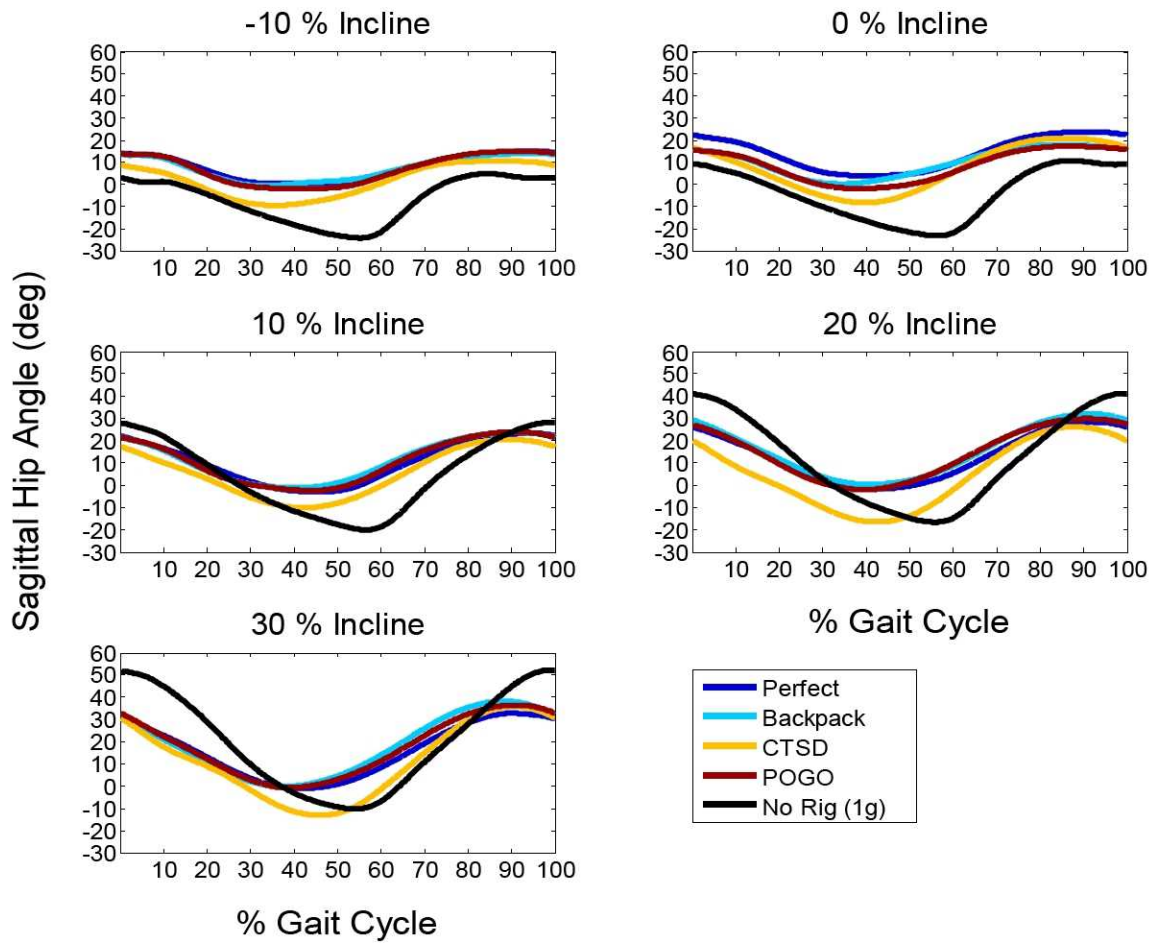

Figure 4-43. Hip joint angle traces over one gait cycle for each CG condition. Each plot is at specific incline.

Differences between the CTSD CG and all others are seen in the comparison of sagittal torso tilt between the conditions (Figure 4-44). As the incline changes from a negative grade to a positive grade, the unsuited torso adjusts its tilt accordingly from a backwards lean to a forward lean to keep the body CG in a balanced position. The CTSD condition does not increase past 10°. The rest of the CG conditions slowly increase the amount of torso tilt as the incline increases. One noticeable difference between the CG rig conditions and the 1-g condition is that the overall range of tilt between the incline conditions is significantly reduced in the CG rig, especially in the CTSD condition.
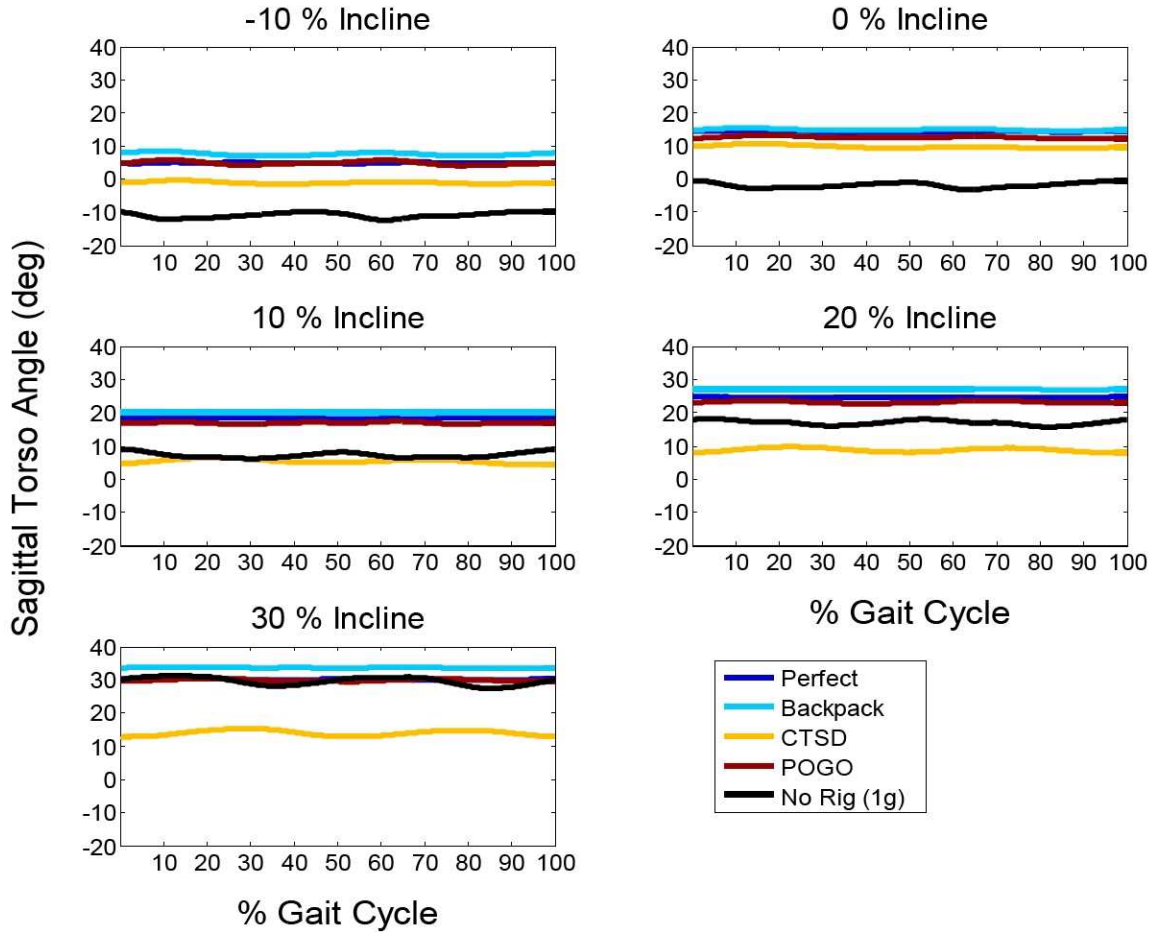

Figure 4-44. Torso angle traces over one gait cycle for each CG condition. Each plot is at specific incline.

4.3.2.4   *Electromyography*

As described previously, only two subjects had a full data set to analyze. For several reasons including problems during testing and lengthy data reduction processes, only the erector spinae of one subject was analyzed for this report and presented as an example.

For the decline condition, all configurations had the muscle activity after the left foot strike (Appendix E). All the CG rig configurations had the activity during the swing phase, but it ended before initial contact. Compared to level ground walking, the amount of high intensity muscle contraction was high. As the incline increased from level, the duration of the contraction increased and the duration of the higher magnitude of contraction increased. The EMG results for the erector spinae at the 10% incline are presented in Figure 4-45. This incline condition was presented because the 20 and 30% grades were not performed for the CTSD CG rig condition. Once again, the 1-g condition showed activation during swing and at initial contact, while the CG rig conditions were primarily activated during swing. Of note was the burst during stance for the Perfect CG rig condition. Interestingly at the highest incline, the CG rig configurations showed higher intensity contractions.
Figure 4-45. Erector spinae muscle activity during a gait cycle. The gray shading indicates the intensity of the contraction.

4.3.3 Subjective Results and Discussion

4.3.3.1 RPE

   With the exception of 1-g data, RPE trends (Figure 4-46) were similar to metabolic trends (Figure 4-3). Mean RPE for the CTSD condition was significantly greater than all other varied CGs for grades of -10, 0, and 10%, although the standard deviation range did have notable overlap with the other CG conditions, which was not present in the metabolic data. At 20 and 30% grade, there was considerable overlap between CG conditions and no significant differences were noted. This could possibly be related to a few subjects that could not complete the higher grades in the CTSD condition. These subjects did not complete the 20 and 30% incline trial because they would have exceeded exertional limits set as test termination criteria. If they were allowed to complete these stages, the mean RPE ratings likely would have been much higher. The 1-g RPE ratings seen at 10, 20, and 30% grade were very similar to the values of other CGs that was not the case with the metabolic data. This indicates that subjects rated RPE differently under different conditions, such as freestanding in 1-g versus offloaded while connected to the gimbal support structure with CG rig. This finding is similar to that of previous studies where RPE was rated differently in the suited and unsuited conditions (5) (1) (2).
Figure 4-46. RPE at different CG conditions during graded ambulation on a treadmill at 0.8 m•s⁻¹.

4.3.3.2 GCPS

GCPS ratings were significantly greater with the CTSD CG (see Figure 4-47) compared to other CG configurations. This was most notable at grades ≤ 10%. At 20 and 30%, there was just enough change in the mean that the CTSD condition would still be considered significantly greater than the other CG configurations, but there was considerably more overlap in the range of ratings. Mean ratings at the CTSD CG indicated that modifications were warranted or required to attain desired performance. Ratings at all other CGs were similar and trended towards either desired performance or adequate performance. In addition, there was a subtle trend for GCPS to increase with grade.
Figure 4-47. GCPS at different CG conditions during graded ambulation on a treadmill at 0.8 m•s⁻¹.

4.3.3.3 Subjective Rating Changes from 30 sec to 3 min

In this study, RPE and GCPS were measured at both the 30-s and 150-s mark of the 180-s trials. Figure 4-48 shows the change in RPE and GCPS from the 30-s mark to the 150-s mark of the 180-s trials during graded ambulation. In over 90% of the trials, the ratings either stayed the same (62% RPE, 82% GCPS) or increased by 1 (32% RPE, 11% GCPS). Unlike the level ambulation trials, the graded ambulation trials required a break to be taken between each different incline to reset some of the data collection equipment. This may account for the increased frequency of the RPE increasing by 1 rather than staying the same. GCPS seems to be less affected by duration, as would be expected.
Figure 4-48. Change in subjective ratings from the 30-s mark to 150-s mark in a 180-s graded ambulation trial (n = 114).

4.4 Exploration Tasks

As discussed previously, one subject from the ambulation trials could not complete the final exploration task and postural stability session due to scheduling conflicts. A subject with previous experience from IST-1 and IST-2 was included as the replacement. From the 108 total exploration test points from all test subjects, seven were either not attempted or led to a GCPS rating of 10 indicating that the subject could not complete the task at that condition.

4.4.1 Biomechanics Results and Discussion

4.4.1.1 Strategy

In the current study, subjects performed a series of exploration tasks, including rock pick-up, shoveling, and kneel-and-recovery. The varying movement strategies adopted by subjects to complete these exploration tasks do not lend well to traditional biomechanical analyses. Therefore, alternative analyses were considered to characterize the performance of these tasks.

Certain methodological limitations prevented customary biomechanical analyses from being provided. For example, all offloaded conditions were performed while donning a 111 kg (245 lb) CG rig with long arms and a significant amount of mass attached to each arm. The CG rig itself therefore may be considered a confounding factor for unsuited subjects, as increased inertial properties associated with it may have caused alterations in movement strategies adopted by the subjects.

As each subject adopted a different strategy to complete the various exploration tasks, analysis of movement during trial performance began with examination of qualitative measures (ie, observation).

This approach was selected to provide meaningful interpretation of exploration task data, given the difficulty inherent in generalizing kinematic analyses of variable adopted movement strategies to a population. Additionally, it was worthwhile to determine if, through a qualitative analysis of subjects' adopted strategy, the system itself and its associated inertial properties had a confounding effect on task performance (eg, CG rig inertia forced subjects to adopt a strategy other than that selected in 1-g).

It should be noted that, in addition to the other CG rig configurations, 1-g (Perfect) CG rig condition was tested for exploration tasks only.

4.4.1.1.1 *Rock Pick-Up Task*

When performing the rock pick-up task, subjects approached and then stood on dual AMTI force platforms (one foot on each force platform), attempting to maintain contact with the force platforms throughout the duration of the task. Subjects performed three trials for each of the various CG rig conditions.

Five of the subjects included in the current study report being right-hand dominant, while one subject is considered ambidextrous. Based on previous testing in the MKIII demonstrator suit and the effect that the offloading system appeared to have on subjects' chosen method of performing the rock pick-up task, it was deemed worthwhile to examine how the current CG rig and gimbal structures affected the adopted strategy of the subjects. For example, it was of interest to examine how the subjects chose to pick up and set down the rock when performing this task, to help determine if the CG rig and gimbal components had an effect on how the subjects approached and completed the task.

All subjects selected the right hand to pick up the rock when performing the task under 1-g, no-rig conditions, thus providing a baseline from which to compare other conditions. As seen in Figure 4-49, not all trials performed under offloaded conditions involved the use of the right hand. For example, approximately 45% of the trials performed at the CTSD CG rig condition involved use of the left hand to pick up the rock. This suggests that while unconstrained (eg, under 1-g conditions) the subjects freely selected the most efficient movement pattern to complete the task; but when performing the task under varying offload conditions in the CG rig, the movement pattern selected was based more on restrictions placed upon the subject by the components of the system offloading them.
Figure 4-49. Hand involvement by subjects to perform the rock pick-up task for all tested conditions. DNC = did not complete.

This observation is further confirmed by qualitative examination of the movement coordination between the upper and lower body to perform the rock pick-up task. Again, consistency is observed in the interaction of movements between the upper and lower body when performing the rock pick-up task unencumbered in 1-g no-rig conditions, in that every trial performed by every subject involved squatting evenly straight down and picking up the rock with the right hand. Table 4-2 presents the frequency of each combination of upper and lower body interaction when performing the rock pick-up task.

Table 4-2. Upper and lower extremity coordination – rock pick-up task

CG condition	Pick-up with left hand			Pick-up with right hand		
	Bend down to L	Bend down to R	Squat straight down	Bend down to L	Bend down to R	Squat straight down
1-g	n/a	n/a	n/a	0	0	18
1-g (Perfect)	0	0	3	6	0	13
Perfect	0	2	4	6	0	6
Backpack	0	0	3	7	0	7
CTSD	0	2	6	3	0	7
POGO	0	0	4	6	0	6

When picking up the rock with the left hand, subjects never bent down to their left. Similarly, when picking up the rock with the right hand, subjects never bent down to their right. One possible explanation for this finding pertains to the need for subjects to maintain balance to complete the task. It may have been easier for the subjects to counteract their reach for the rock with appropriate lower

77

extremity movement (eg, squat down or bend down in the opposite direction). Based on the 1-g baseline findings for this task, one could reasonably assume that the CG rig used in the offloaded conditions introduced extra, artificial inertial factors that had to be accounted for by the subjects when performing the task, thus resulting in the movement patterns observed for these conditions.

Foot placement was observed for each trial, with the goal of determining if subjects were capable of maintaining consistent contact with the force platforms throughout the duration of the trial performed. This examination was performed in an attempt to provide a qualitative estimation of subject stability while performing this task. Stable foot placement was defined, for purposes of the current test, as minimal to no foot movement from the time the task was initiated until the time the task was completed. All trials in the current test performed under 1-g no rig conditions corresponded to stable foot placement by the subjects. Conversely, 50% of the trials performed in the CTSD CG condition and nearly 60% of the trials performed in the 1-g (Perfect) CG condition yielded unstable foot placement. Aside from the 1-g no-rig condition, the Perfect and POGO CG conditions included the most trials in which subjects exhibited stable foot placement on the force plates while performing the rock pick-up task (Figure 4-50).
Figure 4-50. Percentage of performed rock pick-up trials in which subjects demonstrated either stable or unstable foot placement on the force platforms, or did not complete (DNC) the task.

4.4.1.1.2   Kneel-and-Recover Task

Subjects performed a kneel-and-recover task that involved bending down until the right knee came in contact with the ground, then returning to an erect standing posture. Two major techniques were observed (Figure 4-51) when examining performance of the kneel-and-recovery task: a controlled, deliberate movement when rising from a kneeling position (ie, "stand up"), and a jumping technique in which the subjects performed the rise phase via a movement primarily characterized by a disconnect between the feet and the ground upon rising (ie, "jump up"). Kneel-and-recovery under 1-g conditions

typically does not involve rapid, explosive jumping back up to the standing position, mainly due to the considerable amount of muscular effort that would be required to perform such a maneuver.
Figure 4-51. Percentage of kneel-and-recover trials performed in which subjects either did not complete the task, stood up from the kneeling position, or jumped up from the kneeling position.

The preferred strategy under all conditions when performing the kneel-and-recover task was standing up rather than jumping up. As expected, no subjects jumped up from a kneeling position when under 1-g conditions (1-g no rig and 1-g (Perfect)). However, approximately 25% of the trials performed with the Backpack and CTSD settings and over 30% of the trials performed with the POGO CG setting resulted in subjects electing to jump up from the kneeling position. This may be the result of assistance afforded to the subjects by the offloading system, as well as the fact that these CGs often pulled the subjects backward (Figure 4-52). It would conceivably be easier for the subjects to take advantage of the system and jump up if the CG configuration did not allow a shift of their center of mass forward enough to stand up in a controlled fashion with their weight more over the lead leg.

Figure 4-52. Effect of the CG rig ("CTSD" CG configuration, on right) on subject posture at the kneeling portion of the kneel-and-recover task when compared to 1-g no rig controls (on left). Backward lean of the trunk caused by the CG rig, combined with the offload of the subject by the POGO system, allowed subjects to more easily jump up than stand up in certain conditions.

4.4.1.1.3 Shoveling Task

Subjects also performed a shoveling task that, like the rock pick-up, involved the subject standing on a dual force platform set-up (one foot on each platform). Subjects used an Apollo-era-type shovel to move a bean bag from an elevated platform (approximately 50 cm higher than the top of the force plates) to the floor. This approach was used in an attempt to maintain consistency with previous tests in this series. The complexity of the shoveling task resulted in varying interactions between upper and lower extremity segments across subjects, and whole-body coordination was required to perform the task effectively and efficiently. Coupling movement complexity with other test factors, such as offloading the subject via the POGO gimbal, varying CG rig conditions, and limited force platform dimensions on which to stand, may provide some explanation for trends observed in the movement strategies selected for this task. As with the rock pick-up task, examination of foot placement upon the force platforms throughout each trial helped to provide a qualitative assessment of stability during task performance (Figure 4-53).
Figure 4-53. Percentage of performed shoveling trials in which subjects demonstrated either stable or unstable foot placement on the force platforms, or did not complete (DNC) the task.

Stable foot placement on the force plates was observed for all 1-g no-rig trials (Figure 4-53). The 1-g (Perfect) condition also had a high percentage of completed trials in which subjects had observed stable foot placement throughout the duration of the trials. Of the lunar-offloaded trials, subjects maintained stable foot placement the most consistently with the "Backpack" and "Perfect" CG conditions (Figure 4-53). Conversely, over 50% of performed trials for both the "CTSD" and "POGO" CG rig conditions had observable, unstable foot placement by subjects when shoveling.

Several movement strategies were employed by subjects to complete the shoveling task; these varying strategies may have also been the reason for observations of unstable foot placement in certain trials. For instance, subjects varied the position and orientation of the hands on the shovel handle, effectively altering their approach to the task. This may have been the result of the difficulty experienced from trying to shovel bean bags from an elevated platform, as well as the long length of the shovel handle itself, and the subjects possibly attempting to keep the end of the shovel handle from interacting with the CG rig when performing the task. This often led to subjects pushing the bean bag off of the elevated platform rather than actually scooping the bean bag and moving it.

These factors may also have led to subjects trying to scoop up the bean bag from various angles, which frequently caused the entire elevated platform to move. If subjects were applying any weight through the shovel to the platform, and were inherently less stable due to POGO offloading, sudden movement of the platform would have caused an instability that required measures to be taken by the subject to remain under control (ie, alter/re-adjust foot placement) to complete the task.

One other factor to discuss as possibly affecting strategy and therefore stability during shoveling task performance was the interaction between the CG rig and the POGO gimbal. Specifically, a

horizontal bar located at the bottom of the CG rig would move about the roll axis with movement by the subject, causing one side of the bar to come in contact with (and often become stuck against) the POGO gimbal structure (Figure 4-54). Such collisions were only noticed during the Perfect CG condition.
Figure 4-54. Visual comparison of interaction (circled) between CG rig and POGO gimbal. On the left, the horizontal bar of the CG rig is free from contact with POGO gimbal.

Once the CG rig was in contact with the gimbal, subjects would either have to forcefully lean to free the rig from the gimbal, or continue to perform the task without this degree of freedom, therefore leading to an alteration of strategy to complete the task. Either method was associated with some compensatory action that may have in turn affected subjects' stability on the force platforms.

4.4.1.2 Stability

Another method of analyzing the exploration data involved the examination of the center of pressure (COP) in relation to the placement of the feet, the base of support (BOS). For the rock pickup and shoveling tasks, subjects were asked to step on to the force plates, stabilize themselves (eg, allow the mechanical system of the subject, rig, and POGO come to rest), perform the task, stabilize themselves, and step off the force plates. For each frame of data the BOS was calculated using the x, y, and z coordinates of the feet from the motion capture data, and the COP was calculated using the moments and forces collected from the AMTI force plates.

Four metrics were computed and analyzed to determine the effects of varying CG on COP: the percentage of time the COP was outside the BOS, the number of times the COP fell out of the BOS, the average area of the BOS, and the total distance the COP traveled during the task. Each metric is an indicator of the stability of the subject to complete the specific task. More specifically, both the percentage of time the COP was outside the BOS and the number of times the COP fell out of the BOS represents the amount of time and frequency during the trial that a subject was unstable. The BOS was determined from three-dimensional motion capture data for each frame. Thus, solely examining the

percentage of time the COP was outside the BOS and the number of times the COP fell out of the BOS may be misleading. The placement of the feet could change for different configurations thereby effectively reducing or increasing the area that the subject had to support themselves. Hence, examining the average area of the BOS for each frame of data is more representative of stability when examined with the percentage of time the COP was outside the BOS and the number of times the COP fell out of the BOS. The total distance traveled by the COP is also a measure of stability in that the less the COP travels, the greater the stability.

Figure 4-55 is a graphical depiction of the how the metrics for this analysis were computed. The red and blue lines represent the calculated COP for the right foot and left foot respectively. The combined COP total is shown as the green line. The black lines are the maximum area the subject used to complete the task.
Figure 4-55. Example plot of rock pick-up center of pressure trajectory.

The order of testing is important to note as it may have negatively impacted the results. All neurological platform testing was completed first, followed by three kneel and recovers, three rock pickups and three shoveling tasks. Further, the first three conditions were always in the same order: 1-g with no rig, Perfect CG with only the weight of the rig offloaded, and Perfect CG at a lunar weight. The remaining three configurations were randomized. The lack of randomization between conditions may have influenced the results of the stability analysis in that any trends observed may be a result of the order tested and not the parameter in question. Also, one subject was not included in this analysis because no motion capture data was collected for CTSD and POGO CG configurations.

4.4.1.2.1   Rock Pickup Task

The protocol for rock pickup included subjects stepping onto the force plates, stabilizing themselves, bending down, picking up the rock, bending down, setting the rock back down, and stepping off the force plates. However, not all subjects adhered to the protocol. Subject 3 bent to pick the rock up but dropped it down onto the platform without bending back down, thus only completing half of the trial. Therefore data for Subject 3 was carefully scrutinized when comparing his data with the other subjects. Further, for the majority of the trials the subjects performed the tasks on their toes rather than feet planted firmly on the force plates.

The percentage of time that each subject's COP was outside the BOS is shown in Figure 4-56. The CTSD CG recorded the most percentage of time outside the BOS for all subjects. On average almost half of the trial was spent outside the BOS, which may be due to the CG configuration but was more likely because of the CG misalignment with the gimbal axes of rotation. For all other CG configurations, the time spent outside the BOS was minimal.
Figure 4-56. Average percentage of time the COP was outside of the BOS during the rock pickup task.

The results demonstrated that only subject 1 had little difficulty in maintaining stability. Subject 4 had a high percentage outside the BOS in the 1-g condition; a possible reason for this may be because the subject did not stabilize before beginning the task. As the subject stepped on the force plate, he was already bending down to pick up the rock. Only for his first trial did this subject have a high percentage

outside BOS, with the other two trials around one percent. This also may be due to posterior swaying as he stood up from placing the rock down. Subject 3 did not follow the testing protocol by properly replacing the rock as instructed. Therefore, the results showed that subject 3 recorded significantly less percentage outside the BOS compared to the other subjects at the CTSD CG configuration. The Backpack CG configuration for subject 2 resulted in a higher percentage outside the BOS compared to the other subjects. This may be due to several factors such as: configuration being the last tested for the test day and the technique that the subject chose (eg, lunged down instead of bent down) proved to be more difficult. Further, the subject's core strength may have been an issue namely because across almost all conditions the subject recorded on average a higher percentage outside the BOS compared to other subjects.

Figure 4-57 represents the number of times the COP fell outside the BOS. CTSD CG had the greatest frequency of recorded times outside the BOS. Subject 2 scored a higher number due to the alternative method of the subject hopping into a lunge to pick up the rock. Subject 5 was also noted to use a jumping into position technique for the Backpack CG configuration. These higher frequencies outside the BOS for these subjects may be attributed to the sudden movements for which the outcome would be a quick shift in the COP, resulting in the COP falling out of the BOS.
Figure 4-57. Number of times the COP crossed to the outside of the BOS for rock pickup task.

It is understood that a subject widens his stance when he is unstable. This gives the COP more room to move inside the BOS without resulting in instability. From the data, the CTSD CG had, on average, the smallest average area of support and POGO CG had the largest average area of support compared to the different CG configurations (Figure 4-58). From these results it could be concluded that the CTSD CG configuration caused the subjects to have less of a BOS whereas the POGO CG resulted in the subjects creating the largest BOS. The results from the area analysis are useful in validating the other stability metrics. For example, subject 1 recorded the least amount of time outside of the BOS as seen in Figure 4-56, which may be due to the increased area of the BOS (Figure 4-58).
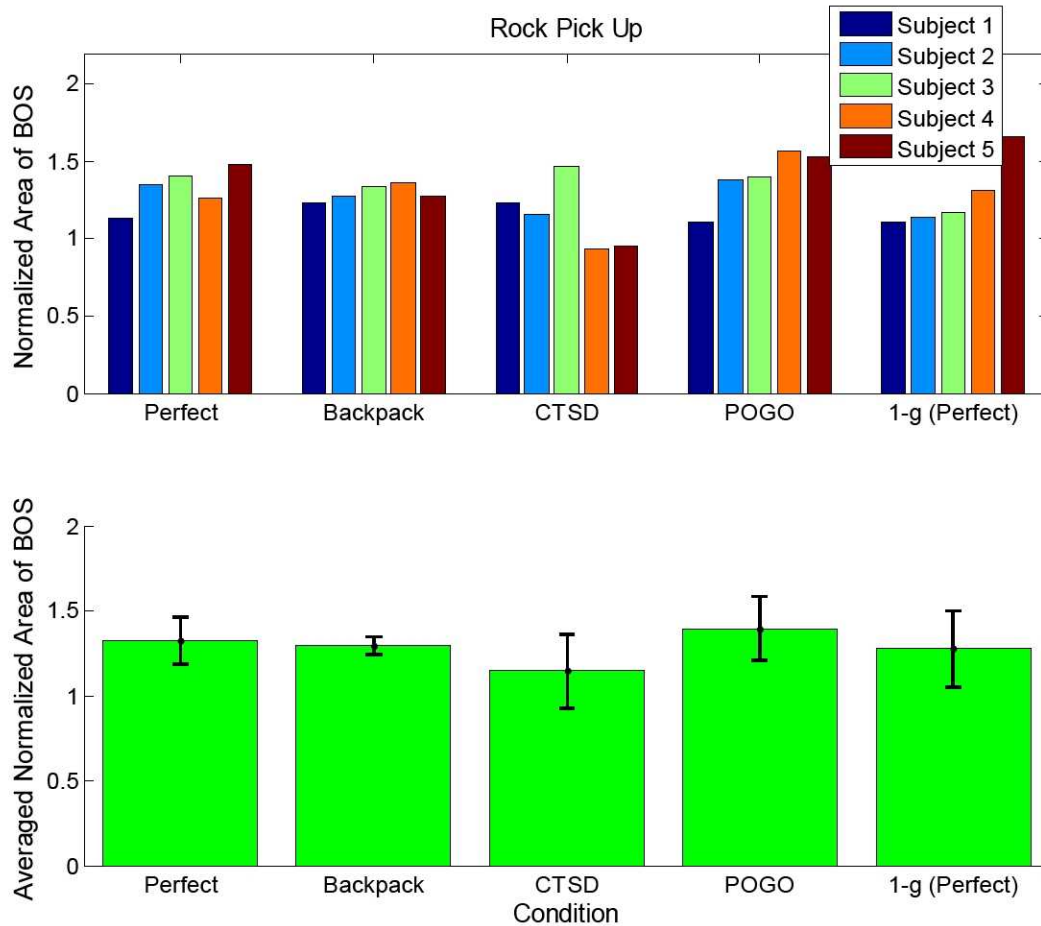

Figure 4-58. Average area normalized to 1-g for the rock pickup task.

When comparing the CG configurations, there were no observable trends for how far the COP travels (Figure 4-59). Looking at individual subject results in combination with the average area results revealed individual stability. For example, subject 4 had one of the largest areas of support, but as seen in Figure 4-59, the COP traveled the least compared to the other subjects. Normalizing the total COP travel to the 1-g condition did not improve the results and revealed no observable trends.

86
Figure 4-59. Average total distance COP traveled during the rock pickup task.

4.4.1.2.2 Shoveling Task

The shoveling task protocol was similar to the rock pickup except that the subject only performed one shovel per trial. Further, this was the last task tested for each condition, so subjects were able to familiarize themselves to the configurations before this task.

The average percentage of time outside the BOS for each subject is seen in Figure 4-60. The results from this analysis revealed no observable trends except that three of the five subjects had some difficulty maintaining the COP inside the BOS for the CTSD CG configuration. The CTSD CG condition may have recorded more time outside the BOS because three of the subjects had a similar method of leaning forward or falling forward when scooping up the lead bag. For example, video evidence demonstrated that subject 3 for this condition used the momentum from stepping on to the force plates to fall forward and that the subject anticipated the inertia of the system to help accomplish the task. Subject 4 recorded the most amount of time outside the BOS. This may be because the CTSD CG configuration was the last one tested for this subject, resulting in fatigue that may have made the task more difficult..
Figure 4-60. Average percentage of time the COP was outside of the BOS during the shoveling task.

Subject 3 had a high percentage time outside the BOS for the Perfect CG configuration compared to the other subjects. A possible reason may be due to the settings of the spider and gimbal of this configuration. The weighted arms of the rig were lower and the right hand corner of the horizontal bar of the CG rig was caught on the gimbal for all shoveling trials for this condition. Another contributing factor could be that this was the first configuration offloaded to lunar weight.

The results from the 1-g condition were unexpected. Four out of five subjects recorded time outside the BOS, albeit minimal. This may have been a result of the subjects keeping their feet in the center of each force plate. The force plates were lined up horizontally to the task setup. Performing the task unsuited gave the subjects greater visibility of the force plates compared to being suited. Thus the subject could easily ensure that they were on the force plates and not near the edges. For terrestrial shoveling, the feet are usually staggered with the foot opposite of the shovel in front. As the setup forced the subjects to perform the task using a novel method, the subjects had more instability. This most likely would not be a method used on the moon.

Figure 4-61 demonstrates how each configuration affected subjects differently. The average data does not correctly represent the results given that some subjects were greatly affected by the different

CG conditions compared to others. Thus one must look at individual subjects. The subjects that had a difficult time with the percentage of time the COP was outside the BOS also were seen to have problems with the number of times the COP fell out of the BOS. Just as the percentage of time outside the BOS data demonstrated, the number of times outside the BOS for the 1-g condition revealed that all subjects except one had on average one to two occurrences of the COP falling outside the BOS. The possible explanations coincide with those given previously for percentage of time outside of the BOS.
Figure 4-61. Number of times the COP crossed to the outside of the BOS for shoveling task.

There were no observable trends for the average area of the BOS as seen in Figure 4-62. By just adding the CG rig, the areas were approximately 1.5 times greater than 1-g. Individual subjects either maintained a similar size BOS or adjusted it depending on the configuration. For subject 5, the configuration with the largest amount of time outside the BOS was CTSD CG. For that subject, the area of support for CTSD CG was smaller compared to Backpack and POGO CGs, which had no falling out of the BOS. Other subjects, such as 2 and 4, kept the area consistent over all configurations even though the COP fell out of the BOS. These findings demonstrate that subjects employed different strategies. Some subjects chose a consistent stance across all conditions while another subject seemed to adjust their stance according to the condition tested.
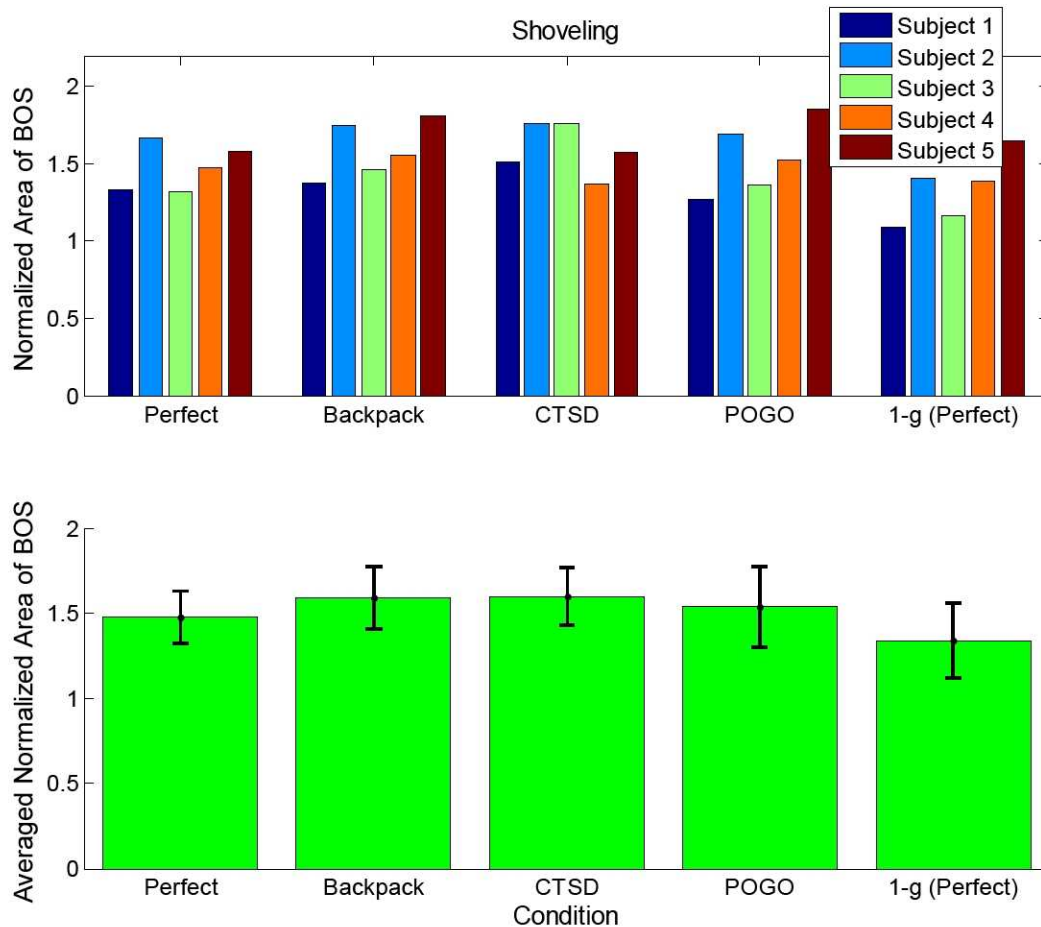

Figure 4-62. Average area normalized to 1-g for the shoveling task.

The total distance traveled by the COP shows that the COP traveled slightly more for CTSD CG than the others (Figure 4-63). Subject 4 had the least traveled COP but also had one of the smaller areas of support and spent a larger amount of time outside the BOS. Subject 3 in the Perfect CG configuration had the largest amount of total travel of the COP, but also, as seen in Figure 4-61, the smallest area of support. The variability between subjects once again suggests there could be interactions between the test environment and strength capabilities. All configurations at lunar offload had, on average, approximately three times greater COP travel than 1-g.
Figure 4-63. Average total distance COP traveled during the shoveling task.

4.4.2 Subjective Results and Discussion

4.4.2.1 RPE

RPE results for the exploration tasks are shown in Figure 4-64. Comparing the 1-g no rig condition to the 1-g with rig offloaded indicated that the addition of the rig increased mean RPE by 2.2, 2.0 and 1.5 units for the kneel/recover, rock pickup and shoveling tasks, respectively. This indicated that notably more effort was required because of the increased inertia of the CG rig. For the varied CG conditions, the CTSD condition had the greatest mean RPE and the greatest variability. There were no notable differences between the Perfect, Backpack, and POGO CG.
Figure 4-64. RPE for short term exploration tasks at different gravity/CG conditions.

4.4.2.2 GCPS

GCPS results for the exploration tasks are shown in Figure 4-65. Comparing the 1-g no rig condition to the 1-g with rig offloaded indicated that the addition of the rig increased mean GCPS by 1.2, 2.0 and 1.5 units for the kneel/recover, rock pickup and shoveling tasks, respectively. These changes indicated that inertial components of the CG rig significantly affected results. For the varied CG conditions, the CTSD condition had the greatest mean GCPS, but the POGO had the greatest variability. Although significantly less than the CTSD condition the POGO CG had the second greatest mean GCPS for all tasks. There were no notable differences between the Perfect and Backpack CG.
Figure 4-65. GCPS for short term exploration tasks at different gravity/CG conditions.

4.5 Postural Stability Results and Discussion

4.5.1 Subject Weight

The effects of the POGO system and varied CG configuration on subject weight are illustrated in Figure 4-66. Subject weights ranged from approximately 142 to 185 lbs before donning the POGO gimbal support structure (Figure 4-66, 1-g). TGAW was largely unchanged by donning the gimbal support structure configured to the Perfect CG and adjusting the POGO offload to maintain equivalent TGAW to what was seen during the 1-g no rig trials. Decreasing the subject-gimbal combination to lunar weight using the POGO system reduced the weight of all subjects to approximately 60 to 70 lbs and reconfiguring the CG locations did not affect the weight in any substantive way.
Figure 4-66. Subject weights measured during SOT 1 trials for each CG/offload configuration.

4.5.2 Quiet Stance Performance

The effects of each CG/offload configuration on postural stability control during the quiet stance tests were initially assessed using the standard clinical measure, EQ score (Figure 4-67). The shaded regions represent the normal 1-g-performance range (5th to 95th percentile) for a large group of test subjects studied under that condition. Scores below the 5th percentile are considered abnormal.

For SOT 1, the standard clinical eyes open Romberg test, it is clear that all the 1/6-g conditions disrupted postural stability, when compared to the Baseline condition and to the normative population performance (Figure 4-67, top). The CTSD CG configuration had the greatest negative effect, with two of six subjects losing balance during the first 20 s of the 100-sc trial, and one of six subjects feeling too unstable to attempt the trial. The POGO system, alone, appeared to have a stabilizing influence, as evidenced by the small apparent performance improvement observed in transitioning from the 1-g no rig condition to the 1-g (Perfect) condition where the weight of the gimbal and CG rig were offloaded. Whether this putative improvement was caused by a posture-stabilizing mechanical or haptic benefit of the POGO support system or by increased task vigilance caused by the stability-threatening load of the POGO gimbal system could not be discerned from the data. However, as neither of these factors should have been changed between the 1-g and 1/6-g offloads at the Perfect CG, it seems likely that the performance decrement associated with this transition was caused by factors related to the offload transition, which could include an unappreciated decrease in the gain requirement for the control-system generating motor responses to counter postural balance errors detected by the visual, vestibular, and somatosensory systems or a reduction in the sensitivity of the somatosensory detectors.

EQ Scores during the SOT 4 trials were generally lower than during the SOT 1 trials, demonstrating the influence of distorting somatosensory inputs on postural stability control (Figure 4-67, bottom). As with SOT 1, CTSD had a substantial negative effect on postural stability, with only two of six subjects performing within the normal range of performances for the 1-g version of this test condition, and three

94

of six losing balance or being unable to attempt the trial. The stabilizing influence of the POGO system was also apparent in SOT 4 as a performance improvement associated with transitioning from the 1-g condition to the 1-g (Perfect) condition. However, no new information allowed discrimination between a potential mechanical benefit and increased task vigilance as the cause. Unlike the SOT 1 trials, there was no obvious decrement in performance associated with the transition from 1-g to 1/6-g. This strongly suggests that the decrement observed in SOT 1 was caused by a reduction in the sensitivity of the somatosensory detectors at the reduced loading level rather than by an unappreciated decrease in the gain requirement for the control-system.
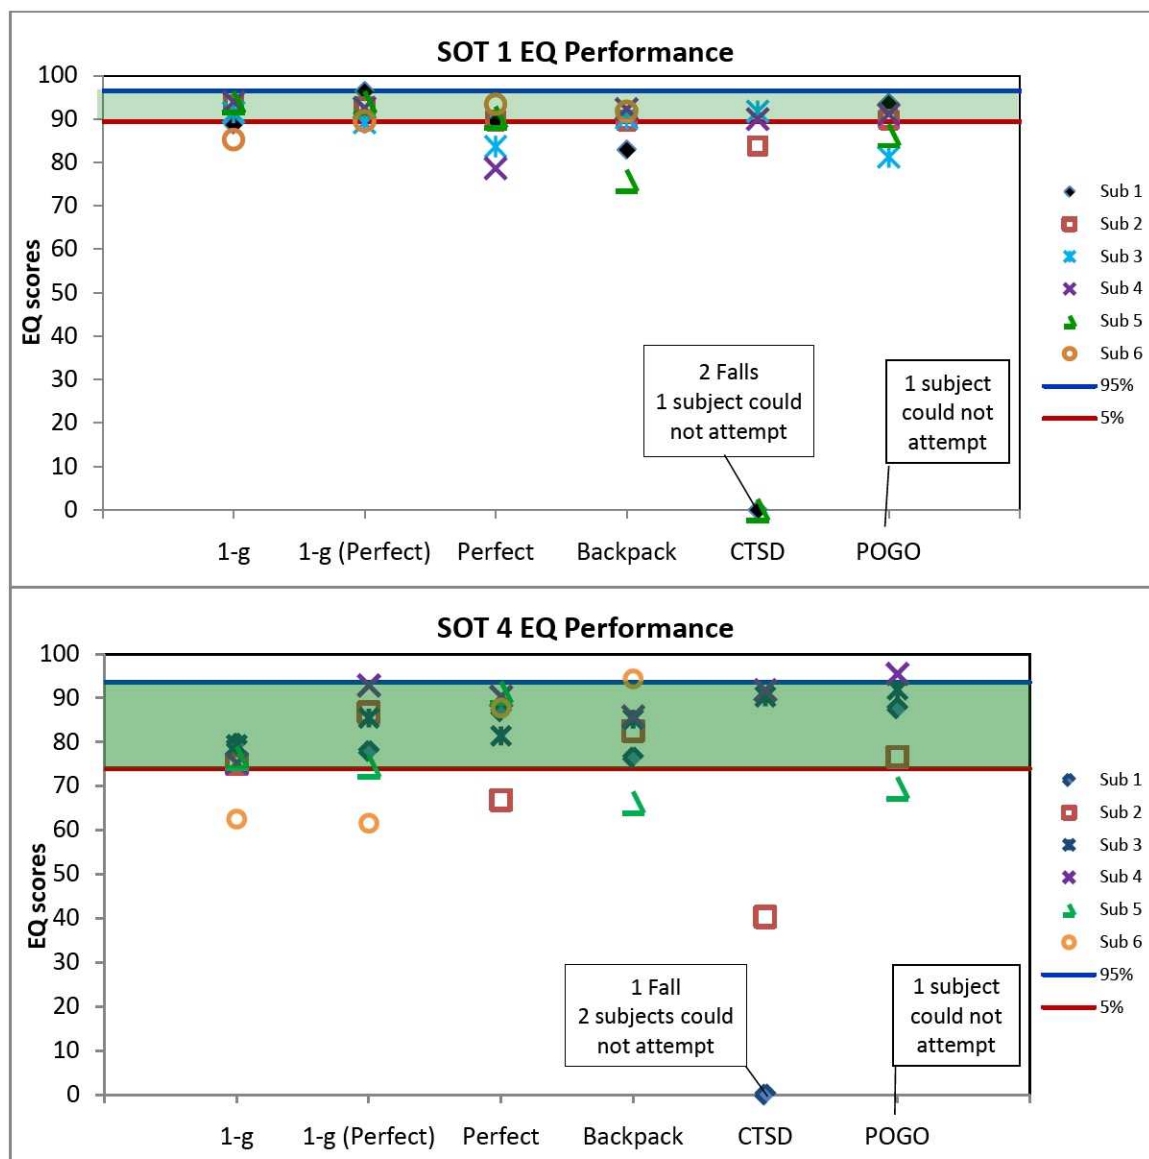

Figure 4-67. Effects of the six CG/offload configurations on each subject's postural stability control performance during SOT 1 (top) and SOT 4 (bottom) trials, as assessed by EQ score. The shaded region represents the normal performance range (5th – 95th percentile) for a large group of test subjects.

EQ Score is a useful index for clinical assessment but may be insufficient to fully assess postural stability control because it is based on only the worst-case body sway (position) excursions over a 20-s

period. We, therefore, computed time-to-contact (TTC), which combines both position and velocity information, over the entire 100-sec SOT trials. Two stability performance indices were derived from the TTC time series: the minimum TTC (TTC_{min}), which is analogous to EQ score in that it estimates the worst-case performance, and the integrated TTC (iTTC), which provides a broader estimate of performance over the whole trial. The effects of each CG/offload configuration on TTC_{min} and iTTC are shown in Figure 4-68 and Figure 4-69, respectively.

For SOT 1, transitioning from 1-g to 1-g (Perfect) did not change TTC_{min} or iTTC, but caused increased variability in each (Figure 4-68 and Figure 4-69, top). As with EQ Score, transitioning from 1-g to 1/6-g reduced postural stability for both TTC indices: TTC_{min} was decreased (Figure 4-68, top) and iTTC was increased (Figure 4-69, top). At lunar gravity loading levels, Perfect, Backpack, and POGO CG conditions resulted in similar performances, but CTSD caused substantially worse performance as assessed by both TTC indices.

For SOT 4, transitioning from 1-g to 1-g (Perfect) caused little change to TTC_{min}, except in one subject who exhibited much more stable performance (Figure 4-68, bottom). However, as with EQ Score, iTTC appeared to be improved by the POGO system (Figure 4-69, bottom). As with EQ Score, at 1/6-g, Perfect, Backpack, and POGO had similar effects on postural stability performance, but CTSD caused substantially reduced performance as assessed by both TTC indices.
Figure 4-68. Effects of the six CG/offload configurations on each subject's postural stability control performance during SOT 1 (top) and SOT 4 (bottom) trials, as assessed by minimum time to contact (TTC$_{min}$). Note that one subject refused to attempt the CTSD and POGO conditions owing to a perceived instability.
Figure 4-69. Effects of the six CG/offload configurations on each subject's postural stability control performance during SOT 1 (top) and SOT 4 (bottom) trials, as assessed by integrated time to contact (iTTC). Note that one subject refused to attempt the CTSD and POGO conditions owing to a perceived instability.

4.5.3 Response to Postural Perturbations

The effects of each CG/offload configuration on postural stability control during sudden postural perturbations were assessed using the TTC indices described above, although the assessment period included only the 9-s recovery period following the perturbation. The effects of each CG/offload configuration on TTC_{min} and iTTC are shown in Figure 4-70 and Figure 4-71, respectively.

The effects of the POGO system and lunar gravity on postural stability during perturbation trials were similar to those observed during the SOT 1 quiet stance trials: stability was improved somewhat by the POGO system and degraded somewhat by increasing the offload. Also, as with the quiet stance trials, the CTSD CG substantially degraded postural stability control during toes-up and toes-down

perturbations as assessed by either TTC$_{min}$ or iTTC, with five of six subjects losing balance or being unable to attempt the TU trials and three of six subjects losing balance or being unable to attempt the TD trials . For the other lunar CG configurations, there was an obvious difference between toes-up and toes-down perturbations, with toes-up being more stability threatening. This was particularly evident with the Backpack CG, which caused substantial performance deficits during toes-up rotations, but not during toes-down rotations (compare, for example, the upper and lower panels of Figure 4-71 for the Backpack configuration).
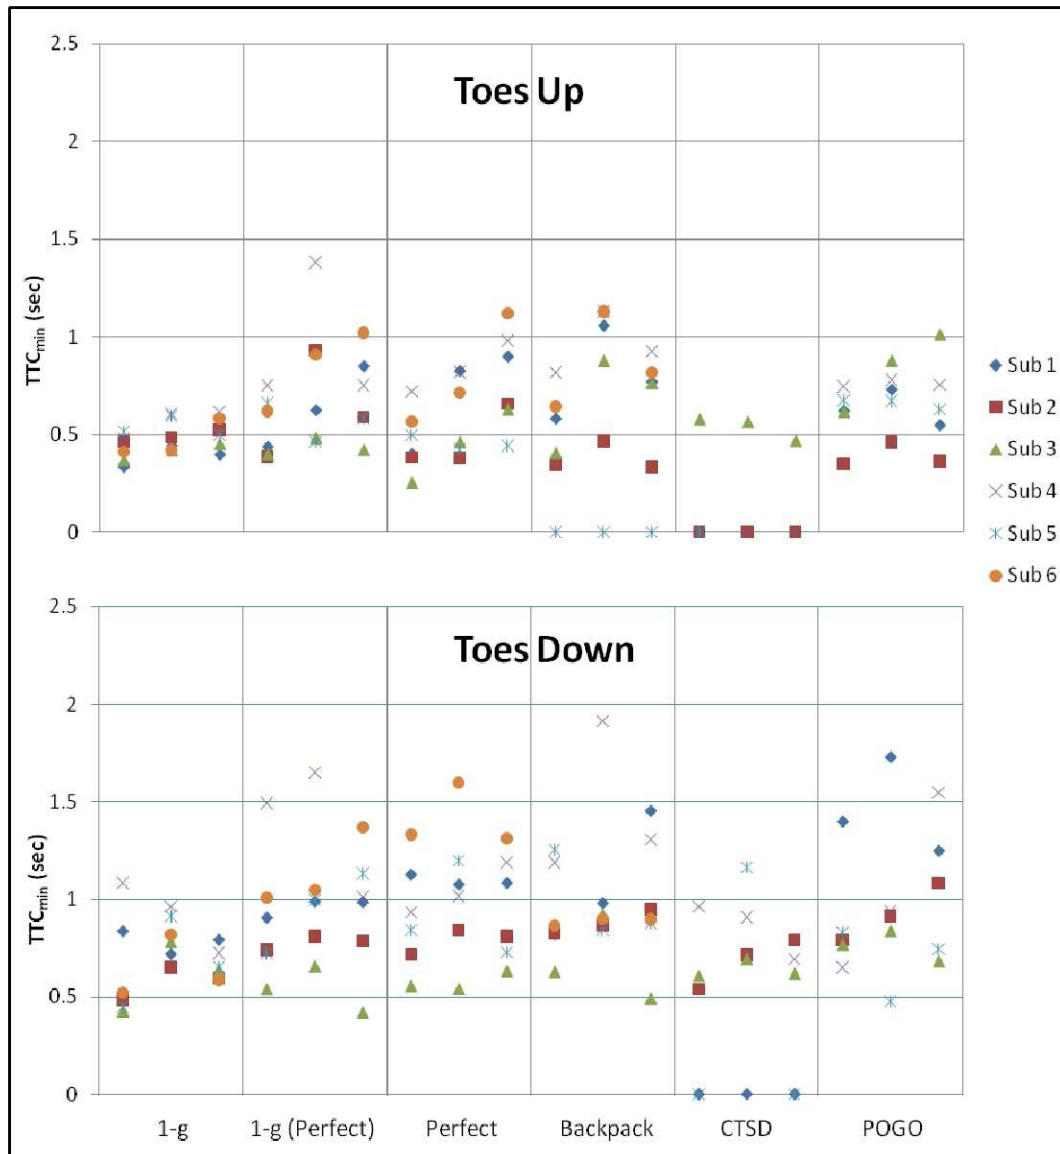

Figure 4-70. Effects of the six CG/offload configurations on each subject's postural stability control performance during sudden Toes-up (top) and Toes-down (bottom) trials, as assessed by minimum time to contact (TTC$_{min}$). Six randomized perturbation trials (three toes-up, three toes-down) were performed at each CG-weight configuration. All trials are displayed in the figure.
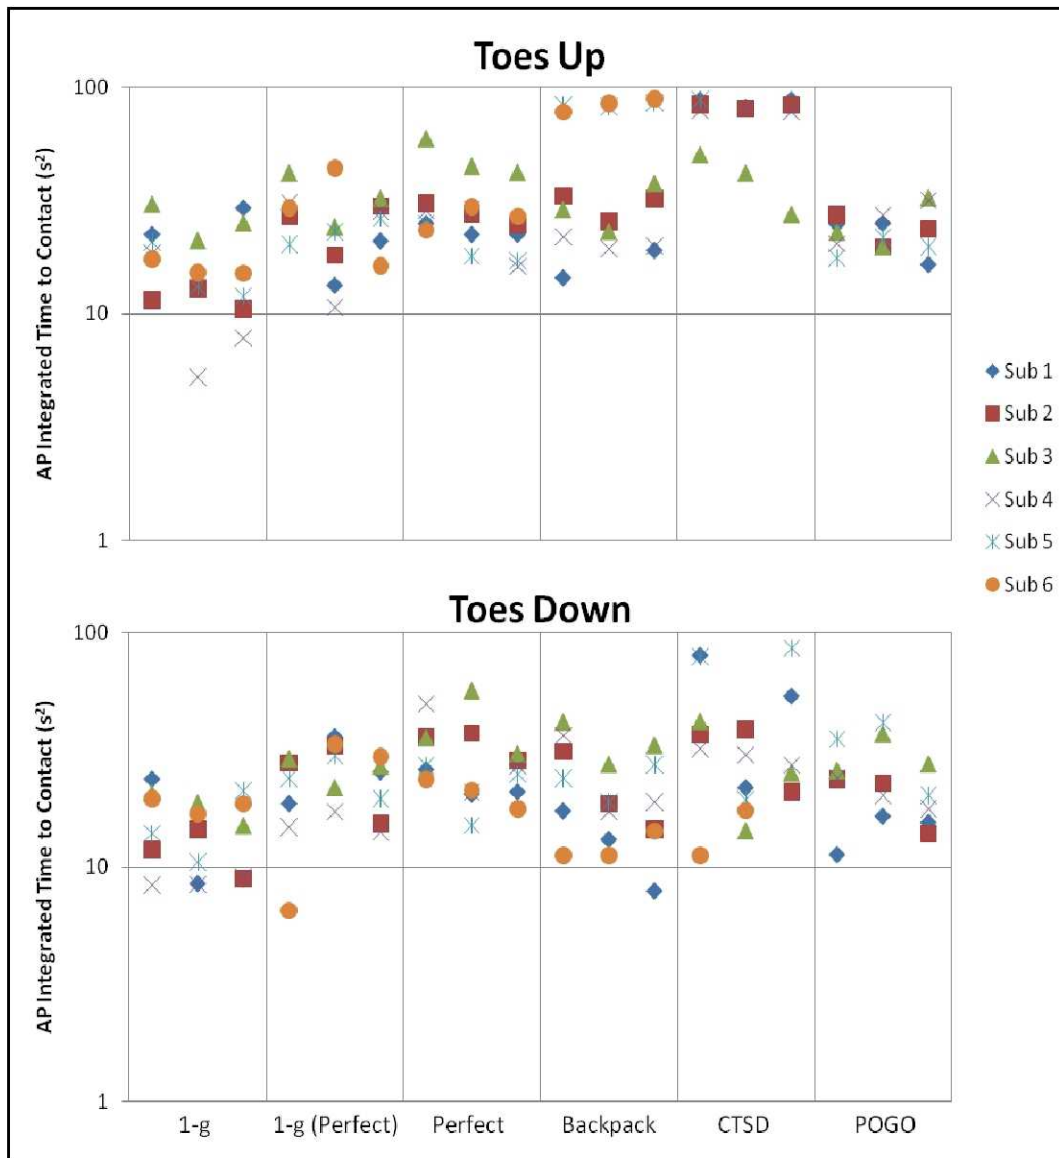

Figure 4-71. Effects of the six CG/offload configurations on each subject's postural stability control performance during sudden Toes-up (top) and Toes-down (bottom) trials, as assessed by integrated time to contact (iTTC). Six randomized perturbation trials (three toes-up, three toes-down) were performed at each CG/offload configuration. All trials are displayed in the figure.

4.5.4 Subjective Ratings

For all of the postural stability trials, the 1-g, 1-g (Perfect) and Perfect CG conditions had similar results for both RPE and GCPS, and were also the lowest compared to the other three CG/offload conditions (Figure 4-72 and Figure 4-73). Both RPE and GCPS were highest at the CTSD CG for all postural tasks. Ratings at the Backpack CG were low for the SOT1, SOT4 and Toes Down tasks, but increased significantly with the Toes Up tasks. This could possibly be related to having more mass further out on the CG rig arms and the subjects thus having to deal with a larger moment of inertia with the perturbation. Results for the POGO CG were generally the next greatest, except for the Toes Down RPE and Toes Up GCPS (Backpack > POGO in both cases).
Figure 4-72. RPE for postural stability tasks at different CG/offload profiles.
Figure 4-73. GCPS postural stability tasks at different CG/offload profiles.

5   Discussion and General Conclusions

5.1   Level and Graded Ambulation

For purposes of general conclusions, level and graded ambulation will be discussed together.

5.1.1   Metabolic Rate

The primary trend to note with metabolic rate was that the metabolic rate was significantly higher with the CTSD CG condition for all ambulation cases. This could be due to two reasons. The first possibility, that the system CG location in relation to the subject's CG was placed in such a way that performance was compromised, is unlikely. The second option, that the system CG location in relation to the gimbal axes of rotation was placed in such a way that performance was comprised, is the likely cause. Post-test analysis involving recalculation of the system CG alignment in relation to the gimbal axes of rotation, clearly showed how the CTSD CG was aligned in a manner that would negatively affect performance (Figure 4-1).

Investigators did not expect the lack of difference among the other CG conditions. Preliminary results from NEEMO/NBL studies indicated that a high/aft CG would negatively affect ambulation performance (3). While this was artificially the case with the CTSD CG, the POGO CG, which was even more high and aft, had very similar metabolic results to the Perfect and Backpack CGs. Testing varied CG conditions using overhead suspension systems such as the POGO increases the complexity because there are two areas of support, the feet and the vertical lift column. Because there are two places where subjects can stabilize themselves, an artificial stabilization may be induced that would not be seen in non-overhead suspension environments (1-g, underwater, or parabolic flight).

Comparing the varied CG data to the 1-g baseline shows a clear linear trend for the varied CGs at 1/6-g, whereas a second order polynomial relationship was a better fit for the 1-g data. The second order relationship is needed at 1-g due to the variation in energetics between a walk and a run. The linear relationship for the varied CG conditions indicates that there was no change in the energetics required to ambulate at speeds ranging from 0.4 to 2.5 $m \bullet s^{-1}$.

5.1.2   Kinetics

A notable increase was seen in normalized mean peak GRF values for 1-g trials with an increase in ambulation speed, especially at 2.1 and 2.5 $m \bullet s^{-1}$ (i.e. running trials). Conversely, normalized peak vertical GRF for all CG rig conditions tended to plateau after subjects reached a 1.7 $m \bullet s^{-1}$ ambulation speed. For the incline trials, greater peak vertical GRF may have been present in the 10% decline as a result of the body having further to fall with each step, attempting to control this descent, and maintaining stability while walking downhill. For this study, no definitive conclusions can be drawn regarding the effect of the individual CG rig settings on GRF during ambulation at varying speeds.

The variability of normalized mean peak GRF data across subjects for CG rig conditions was notably greater than for the 1-g condition for all ambulation speeds and inclines. The CG rig data differs greatly from 1-g running and walking data (13). Whereas a 1-g GRF doesn't plateau until sprint speeds, the CG rig GRF plateaus at a moderate walk. This may be because ambulating at these varying speeds and grades while offloaded with a large attached mass altered the gait patterns adopted by subjects. There was a decrease in GRF with an increase in incline. This is in large part because the force platform in the

treadmill only records forces normal to the treadmill surface. As the incline is increased, a larger part of the GRF will be incorporated into the anterior/posterior shear force, which is not registered by the platform.

One of the major issues at work in this testing environment is the fact that the weight of the CG rig system and subject are offloaded to lunar gravity, but mass and inertia of the subject and CG rig remain unchanged. This plays into effect when looking at CG excursion in the test environment and how the subject is compensating for the large inertial load. Recent studies have found that reducing CG excursion in normal 1-g walking did not decrease energetic cost, but actually increased it (16) (17). However, with an increased mass, the subject is forced to either expend more energy to get the same performance or reduce performance to save energy requirements. Kinetic energy in this case is derived from inertia, mass, linear velocity, and angular velocity terms (Equation 1). As the kinetic energy terms and mechanical work terms are interchangeable, we can consider an increase in system energy a direct result of work done by the subject, or POGO (see Appendix D for variable explanations). Equations 2 and 3 show the interchangeability of work and energy in a dynamic system.

$$KE = \frac{1}{2}mv^2 + \frac{1}{2}I\omega^2 \qquad \text{(Equation 1)}$$

Where,

$$\frac{1}{2}I\omega^2 = I\alpha\theta \qquad \text{(Equation 2)}$$

and

$$\frac{1}{2}mv^2 = mad \qquad \text{(Equation 3)}$$

U.S. Army backpack studies have shown that subjects try to optimize energy expenditure with increased mass by reducing angular movements with the torso, but not necessarily by reducing vertical CG excursion. One study showed that joint rotation and vertical excursion of the CG during initial contact increased as a function of speed but not load (22). These results would suggest that normally a human will maintain the same CG vertical excursion across the speeds tested regardless of unsuited 1-g or CG condition. This constant level of CG excursion is most likely a result of increased metabolic cost due to a deviation in normal gait mechanics. However, this was not observed to be the case in the current test environment. This lack of relationship between CG vertical excursion and speed indicates that the current mechanical system (CG rig, gimbal, POGO) is restricting normal adaptation in gait mechanics.

However, it must be pointed out that the mass increase in this study was actually much greater than could be studied under normal 1-g conditions. This adaptation may have resulted from the subjects being incapable of accelerating the system mass (CG) faster as the treadmill speed increased, and; therefore, plateaued at a 'maximum' point.

The CG rig versus subject CG data shows that the CG rig and subject are acting somewhat independently of one another (Figure 4-9). If you simplified the system and modeled it (Equation 4) as two separate masses connected by simple linear springs (ignoring the friction and damping) we begin to

see the independent and dependent nature of the test system. Figure 5-1 shows a diagram of the simplified system with subject (m_1) and the CG rig (m_2). In this simplified model the subject is the driving force of the system and the POGO is a passive, constant force.

$$k_1 x_1 + m_1 \ddot{x}_1 + k_2 (x_1 - x_2) + m_2 \ddot{x}_2 = 0 \qquad \text{(Equation 4)}$$
Figure 5-1. Illustration of a simplified diagram of the CG rig and subject mass-spring system

Figure 5-2 shows the resultant simulation data from the simplified system. From the simulation data we can see that because the two masses are nonrigidly attached to each other, they do act independently to some extent.
Figure 5-2. Simulation data of the previously mentioned mass-spring system. The blue line the displacement of a sine wave that is driving the m_1 element (subject), the red line is the resulting displacement in the m_2 element (CG rig).

In a system like this complex interactions make it difficult to predict the state of the second mass. Likewise, in the actual CG rig system, it is equally difficult to predict the interactions between the subject and the CG rig, making accurate calculations of system outputs impossible without a detailed model. The second issue with such systems is that the second mass element (m_2) has more energy than the driving mass element (m_1). This is similarly seen in the actual system (Figure 4-9) and may also be a

factor in the reduced CG excursion observed as subjects attempt to reduce the amount of energy in the CG rig and reduce impacts with it as speed increases.

IST-3 data showed similar trends of CG excursion reduction with the CG rig conditions as compared to the unsuited 1-g condition. The reductions at the faster speeds were most likely due to the subject compensating for the very large inertia of the CG rig and attempting to reduce the energy expended during ambulation. The IST-3 test results for lower extremity joint rotations increased with speed and allowed the body to increase speed while keeping the CG excursion minimized were also similar to the reported studies (22). However, at the slower speeds, an increase in CG excursion was seen, most likely as the result of ability to build up a large momentum with the increased mass of the mechanical system at a reduced cost because of the constant weight offload. Once this mass is put in motion, the subject can then take advantage of the large inertia of the POGO system and effectively reduce energy expenditure as the combined system's CG completes its trajectory.

The first major limitation to this study is the amount of compensation required by the subjects due to the inertial characteristics of the gimbal and CG rig, which were much larger than an actual suit and PLSS. Therefore, the data can only be looked at as a trend.

A second major limitation is shown in the CG excursion traces as a difference between the CG rig and the human body. The trace shows both a greater level of kinetic energy in the mechanical system than the subject's body, and it also shows a phase difference. This out-of-phase behavior shows that the POGO system with the CG rig is not able to follow human motion closely enough resulting in small collisions of the two masses. These collisions will be consciously minimized by the subject in an attempt to minimize the energy input from the body into the mechanical system. This minimization is accomplished by compensation in the gait mechanics.

A third limitation could be that of the slow system oscillations represented by the slower waveform of the average CG over the trial period (Figure 4-11). This vertical translation also will influence gait biomechanics by increasing or decreasing joint rotations to stretch or contract the total leg length to accommodate the change in distance from the pelvis to the floor as the average distance of the subject CG to the floor changes. This hypothesis is unproven and could be influenced by small, dynamic changes in the treadmill pitch. Unfortunately, no reference data was taken for the treadmill during the trials.

5.1.3 Temporal-Spatial Characteristics

A consistent decrease in mean stance time was observed with increased ambulation speed for all tested conditions. Additionally, the variability (ie, standard deviation from mean values), across tested conditions, notably decreased with increased ambulation speed. With the exception of the "POGO CG" condition at 10% decline ambulation, mean stance times for all CG rig conditions were less than those for the 1-g, no rig condition across the tested surface grades.

A modest decrease in mean-step width was observed with increased ambulation speed across all tested conditions. Mean-step width for the 1-g condition was consistently lower than mean-step width for the varying CG rig conditions at varying ambulation speeds, suggesting greater stability during ambulation under 1-g conditions. Increases in step width in the CG conditions in comparison to the 1-g condition may be due in part to the effects of the donned harness associated with the CG rig used in the current study. This harness used support straps around the upper thighs that may have altered subjects' preferred gait patterns by forcing the legs into a wider stance. Minimal differences in mean-step width

across varying surface grades were observed for the 1-g, no rig condition. All mean values for this condition corresponded to a step width of approximately 0.1 to 0.15 m. Mean-step width values for all varying CG conditions were larger than values for the 1-g condition (Figure 4-13 and Figure 4-36). The greatest increases occurred at the -10% decline ambulation condition. This may be the product of several factors, including the aforementioned effects of the harness on subjects' adopted gait, and the difficulty inherent in ambulating down a -10% grade while offloaded to lunar gravity in an CG rig that involved considerable effort by the subject to maintain a stable gait pattern.

5.1.4 Kinematics

Differences seen in gait mechanics when walking over ground compared to walking on a treadmill (23)are small and generally constant (although changes are different for males and females), allowing for substitution of one test environment for another when studying gait mechanics.

5.1.4.1 Speed vs. CG Condition and Offloading Mechanics

The gait kinematics of the subjects studied are considered to be normal (without significant pathology). Kinematics of the lower body of the IST-3 subjects at the 1.3 m•s^{-1} speed were closely aligned to published normative data taken at an average 1.3 m•s^{-1} (2.9 mph) (14) (24). Changing the gait speed affects the gait kinematics by requiring greater power output from the body as speed increases.

Little change was observed among CG conditions across the varied speeds for the lower body kinematics. One study showed there was a reduction of joint rotation for subjects while wearing a backpack from the no-pack condition across walking speeds (25). However, this study also showed an increase of joint rotation across both rig and no rig conditions with the increase in speed. The lack of difference between the CG rig conditions would indicate that there was no change to compensation strategy.

Lower body gait kinematics are expected to change in simulated, reduced-gravity environments as body weight support is increased. These changes stem from the reduced dependence on loading to produce forward and vertical motion. Previous studies showed the kinematic changes in the lower-body joints as body-weight support was increased from 10 to 70% (26) (27). Changes observed in the IST-3 test between the unsuited 1-g and CG rig conditions followed similar trends to those reported, but the changes in the IST-3 were much greater than the changes in these two studies in both angle magnitude and time of occurrence (26) (27). At the 1.3 m•s^{-1} speed, there was a shortening of the time to end contact in the gait cycle, a shortening of the hip and knee angles, but an increase in ankle angles. These changes no longer allow the body to produce large propulsive forces in the forward direction because of the small horizontal component of the vector from the ground-contact point to the center of mass (Figure 4-23 and Figure 4-24). This would indicate a reduced dependence on forward propulsion, but a continued dependence on vertical propulsion. CG conditions at all speeds were similar to the unsuited 1-g running-speed ankle kinematics. This similarity illustrates the mechanics being used in the POGO. While running, the body contracts the anterior and posterior shank muscles to increase the stiffness of the ankle, allowing for more efficient energy storage and transfer. The fact that while on the POGO the same strategy is implemented for the CG rig conditions means that the subject was no longer constrained by normal walking biomechanics and could use the more efficient energy storage and transfer system of a stiffened ankle joint.

Given this information, we are left with a conundrum: have the subjects taken advantage of the treadmill velocity (ie, a moving reference frame), or are they still producing actual propulsion forces in a

reduced amount commensurate with the decrease in gravity? Would a person restrict their power output on the Moon and conserve all possible energy or use the available power to their advantage and increase their traveling speed? How do we test the change? Currently we can't measure shear forces and verify our proposition. However, logic suggests that if the subjects took advantage of the true lunar environment, they would still produce their normal propulsive forces, as they still have the full amount of muscular power generation possible. They could do two things: (a) increase both vertical and horizontal-force generation proportionally, as they would in a 1-g environment, or (b) increase the horizontal-force generation, but not the vertical as they no longer need the large vertical reaction force in a reduced-gravity environment to elicit the same horizontal movement outcomes. Unfortunately, the subjects' data did not fit to our logical estimations of change in gait for the changing environment, nor did they continue to follow normal 1-g gait mechanics. C. R. Taylor found that when humans adopt a jumping mode of ambulation, their jump frequency does not change from jumping in place to increased velocities on a treadmill (28). This paper also showed little change in peak GRF values between speeds, however, the loading duty cycle decreased with speed. Given these facts, it is apparent that the IST-3 subjects were able to take advantage of the treadmill belt velocity by continuing to jump vertically with little extra effort to travel horizontally (Appendix C). In an over-ground situation the subject would have to increase both horizontal and vertical forces to increase their speed and/or linear distance traveled. One of the major factors that allows subjects to possibly take advantage of the relative treadmill belt velocity is the inertia of the overhead POGO cylinder. This cylinder stabilizes the subject, allowing them to jump vertically without having the necessary forward propulsive force that would normally be required to remain on the treadmill at a given velocity.

Torso tilt of normal gait follows a pattern of flexion and extension, as muscles of the legs and torso pull and push the hip as the body makes initial contact with the floor then progresses into mid-stance (24). As the speed increases for the unsuited 1-g condition, the magnitude and timing of the tilting ROM increases accordingly as more energy is put into the system and the gait patterns change (29) (30). Tilting in the CG conditions for this study was very minor in comparison and was out of phase by close to 90°. For the CG conditions, the torso remained in a permanently forward-tilted state. The CTSD condition was the exception where at faster speeds the tilt offset was reduced to a near neutral point. The POGO and gimbal system causes the subject's torso to take on a static-tilt angle as the lifting forces and CG align themselves. The system may also impede the subject from dynamically tilting at the hip joint by increasing the difficulty to perform that motion. One theory is that most of the reduction in tilt will be due to the gimbal's sagittal pivot point being out of alignment with any of the body's joints, thereby increasing the force needed to tilt the torso dramatically. Another theory links most of the reduction in tilt to the overhead mass of the POGO pneumatic cylinder. To bend forward, the subject must pull the POGO pneumatic cylinder forward and down, which increases the force needed to tilt the torso. The constant tilt offset is created by the subject and the CG rig and gimbal pitching forward to reduce any internal moments and acquire its static equilibrium position. Both of these events restrict the body from using its normal strategies and dynamics when ambulating (Figures 4-23 and 4-46). The exception to this was the CTSD CG, which seemed to compel an upright posture during all test conditions, most likely because the system CG was located high and aft of the gimbal axes of rotation.

5.1.4.2 Incline versus CG Condition

Walking on a incline or decline changes the basic mechanics of ambulation as your joints are required to bend more to raise your foot for the next step on an incline or less when letting it fall further in a decline. The unsuited 1-g conditions follow closely to reported normative data for walkway and stair ascent and descent (Figure 4-38 through Figure 4-44) (21) (31).

At the -10% grade, the ankle flexion ROM data for the CG conditions were closely aligned to the unsuited 1-g condition. Beyond this specific incline and joint, there were large differences in magnitude between the CG conditions and the unsuited 1-g condition. Again, the CTSD condition showed a high level of change over the range of inclines whereas the other CG conditions remained relatively static. All CG conditions showed the same general trends in changes of ROM with change in incline, except for the torso-tilt angle. The torso-tilt ROM did not show any agreement in trends as the incline was changed.

However, the actual angle traces show stark differences between the unsuited 1-g condition and the CG conditions. The ankle angle traces had the worst comparison and showed little in common in both shape and timing. This was primarily due to the subjects never reaching full foot contact with the floor in the CG conditions and remaining on their toes the entire time. The hip and knee angle traces showed better similarity between CG conditions and the unsuited 1-g condition, but still held prominent differences. Given these facts it is safe to say that there is little in common between the CG conditions and unsuited 1-g condition as far as gait mechanics adaptation is concerned. Minimal changes were seen among any of the CG conditions, the exception being the CTSD. Across the CG conditions adaptation in the ankle and hip mainly occurred as an increase in ROM. For the knee, the CG showed greater change in shape and timing over the inclines and from each other.

As incline changes, there is a shift in the GRF with respect to the location of the hip joint (32). With increases in incline for normal gait, the foot is placed farther out in front of the body at initial contact, increasing the hip moment, and just the opposite for declines. The torso is also tilted forward in an attempt to shift the CG forward, thereby reducing the net hip moments, the opposite being true for declines. The increases in the lower-body angles for the CG conditions are simply a result of the subjects making changes to accommodate the need for a greater height requirement for gait at an incline and not as a result of compensation to produce more efficient gait. These facts would imply that there was little adaptation occurring for the CG conditions as other adaptive methods were not available to the subjects as a result of the CG rig, gimbal, and POGO restrictions.

5.1.5 Electromyography

For comfortable to fast walking speeds, the erector spinae is active during the swing phase and right before initial contact (33) and for level ambulation, the 1-g unsuited trials for the representative subject followed this trend. On the other hand, all CG rig trials above 1.7 $m \bullet s^{-1}$ only showed muscle activity during the swing phase. This may have been because the subject had a reduced GRF as compared to the 1-g unsuited condition or as a result of the altered gait patterns (lack of heel contact) and; therefore, had a reduced need for spinal stability. As speed increased the duration of activation decreased, possibly because of an increase in cadence and a decrease in swing motion.

The decline and highest incline for the CG rig configurations had a high percentage of high intensity contraction during the active segments. There was a substantial reduction of low-level activation at these inclines. The erector spinae may have been contracting at a high intensity and long duration to maintain balance. Some differences were seen among the different CG rig conditions, but none that were uniformly consistent across conditions.

The analysis of the erector spinae data proved useful in the understanding of the treadmill data. This muscle has a primary role as a core stabilizer during ambulation. Upon changing the CG, it was hypothesized that the erector spinae response would adapt accordingly by increasing activity, but such a

change was not seen for the analyzed subject. The addition of the CG rig and then offloading the subject had a large influence on the activation of the erector spinae.

5.1.6 Subjective Ratings

Subjective rating trends followed the metabolic data trends with respect to the varied CG conditions. RPE was clearly rated differently in and out of the CG rig, which is consistent with other data showing different RPE ratings in and out of the MKIII suit. This finding indicates that while RPE alone may be highly correlated with metabolic rate, it may only be specific to certain test conditions and any model expecting to use RPE to predict metabolic rate should be limited to certain conditions or employ an additional factor describing different conditions for which the data was collected.

To model VO_2 based on subjective ratings, the 1-g data was not included, leaving only the varied CG conditions. VO_2 was predicted from the subjects' RPE and GCPS. Mixed-effect regression analysis was used to model VO_2 from RPE and GCPS scores, including subject-level grouping to accommodate for the dependence in the data (ie, repeated observations within subjects) and a random intercept term to allow subjects to vary randomly on the y-intercept of the model. The model residuals appeared normally distributed with constant variance over the range of the outcome, suggesting that the transformed data are appropriately analyzed with these techniques.

The model revealed that both RPE and GCPS predictors made significant variance contributions to VO_2 in this multivariate context ($P < .05$), with the highest relative contribution observed for the RPE predictor. RPE scores were positively correlated with VO_2 and GCPS scores were negatively associated with VO_2 in this model. Model predicted and observed VO_2 values are shown in Figure 5-3. Variation in VO_2 seen per unit of RPE was notably improved by the model.
Figure 5-3. Model-predicted VO_2 (red) and observed VO_2 (blue) with respect to RPE.

While these effects are statistically significant to traditionally held scientific standards, the reader is reminded that they are based on a very small sample of $n = 6$ astronauts. We remain cautious about making inferences to the larger astronaut population or outside of level ground ambulation until these results can be replicated in future work.

Another interesting finding from the ambulation data was that subjective RPE and GCPS ratings tended to either stay the same or increase slightly by one unit on the rating scale from a measurement taken at the 30-s mark to the measurement taken at the 150-s mark of a 180-s trial. For RPE during ambulation trials, 68% of the ratings stayed the same and 26% increased by 1. For GCPS during ambulation trials, 82% of the ratings stayed the same and 12% increased by 1. As would be expected, GCPS ratings were less affected by trial duration. While this may be a good indication of what generally happens with these ratings, these findings are only applicable to ambulation data. More research will be needed to determine if RPE can be applied to different types of tasks, higher intensity tasks and tasks of less than 30-s duration.

5.2 Exploration Tasks

Three different types of exploration tasks were performed, including a rock pickup, shoveling, and kneel and recover. It is important to note that all of these tasks were performed in a fashion that was intended to be similar to previous and concurrent studies and thus are somewhat different from how they would be performed during an actual EVA. Bags filled with lead shot were used as "rocks" and they were picked up and shoveled off of a significantly elevated surface rather than the ground. The kneel and recover did require the subject to bring his knee down to the ground, but it is unlikely that this task would be performed alone but rather would be a portion of a task involving picking something up off the ground or using a tool close to the ground. Future tests should attempt to perform EVA tasks in the most realistic way possible first and then modify that with an alternate performance method only if it was not possible to complete the task. With this method, there will be data on both realistic EVA tasks and modified EVA tasks from which to draw conclusions and develop forward work and recommendations.

5.2.1 Strategy

The varying movement strategies adopted by subjects to complete the exploration tasks did not allow for customary biomechanical analyses to be performed. Therefore, a qualitative analysis of adopted strategy was employed to characterize the performance of these tasks. This approach was incorporated to provide meaningful interpretation of exploration task data, given the difficulty inherent in generalizing kinematic analyses of variable adopted movement strategies to a population. Additionally, this analysis was used to provide an initial, observation-based assessment of CG rig and gimbal components, and to determine if these components had any confounding effects on task performance.

For the rock pick-up task, all subjects selected the right hand to pick up the rock when performing the task under 1-g, no-rig conditions. However, not all trials performed under offloaded conditions involved the use of the right hand, suggesting the movement pattern selected under these conditions was affected by restrictions placed upon the subject by the components of the offloading system components. This finding was further confirmed by observation of the movement coordination between the upper and lower body to perform the rock pick-up task. Under offloaded conditions, when picking up the rock with the left hand, subjects never bent down to their left. Similarly, when picking up the rock with the right hand, subjects never bent down to their right. One possible explanation for this finding pertains to the need for subjects to maintain balance to complete the task. Based on the 1-g baseline findings for this task, one could assume that the CG rig used in the offloaded conditions introduced extra, artificial inertial factors that may have affected subjects' balance and; therefore, their movement strategy.

All rock pick-up trials in the current test performed under 1-g no rig conditions corresponded to stable foot placement by the subjects. However, half of the trials performed in the CTSD CG condition and nearly 60% of the trials performed in the 1-g (Perfect) condition led to unstable foot placement by subjects. Again, this may be attributed to balance being affected by the CG rig and gimbal structures offloading the subjects.

During the kneel and recover task, subjects either stood up from the kneeling position or jumped up. Kneel-and-recovery under 1-g conditions typically does not involve rapid, explosive jumping up to the standing position mainly due to the considerable amount of muscular effort that would be required to perform such a maneuver. It is possible that on the lunar surface, astronauts may be able to more easily jump up than stand up from a kneeling position. However, the to-be-determined ROM requirements of a planetary suit, as well as the demands and objectives of the specific lunar sortie task will play large roles in the crewmembers' adopted strategy and overall task performance. While all 1-g no-rig trials involved standing up from the kneeling position, approximately 25% of trials performed with the "Backpack" and "CTSD" conditions and over 30% of the trials performed with the POGO CG involved subjects jumping up from the kneeling position. This may be the result of assistance provided by the offloading system (ie, for these CG's, subjects often felt pulled backward), thus potentially making it easier for the subjects to take advantage of the system and jump up. If the CG configuration were to have kept a subject's center of mass forward enough, it may have been easier to stand up.

Performance of the shoveling task resulted in varying interactions between upper and lower extremity segments across subjects, and whole-body coordination was required to complete the task. The observation of foot placement upon the force platforms throughout each trial helped to provide a qualitative assessment of stability during task performance. Stable foot placement on the force plates was observed for all 1-g no-rig trials and approximately 85% of the "Perfect-rig offloaded". This may be because while the CG rig was offloaded, subjects tended to keep a 1-g footprint on the ground.

Over 50% of trials for both the CTSD and POGO conditions had observed unstable foot placement by subjects. Several movement strategies were employed by subjects to complete the shoveling task; these varying strategies may also have been the reason for observations of unstable foot placement in certain trials. For instance, subjects varied the position and orientation of the hands on the shovel handle, effectively altering their approach to the task. This may have been the result of the difficulty experienced from trying to shovel bean bags from an elevated platform, the long length of the shovel handle itself, and/or the subjects attempting to keep the end of the shovel handle from interacting with the CG rig when performing the task. This often led to subjects pushing the bag off of the elevated platform rather than actually scooping the rock and moving it. These factors may have also led to subjects altering their movement strategy, including movement of the shovel platform, and interaction (ie, contact) of the CG rig and the gimbal structure.

5.2.2 Stability

The CTSD CG resulted in the most time spent outside of the BOS, but on average had a smaller area of support. The smaller area of support may have been why the time outside the BOS was high for this condition. However, as discussed in previous sections of this report this result may not be solely due to CG placement. Subject strength and method play an important role in the ability to control the COP. As seen with subject 1, who had the fewest occurrences of the COP outside the BOS, the distance the COP traveled was comparable to the other subjects, but the area of support was much larger. Further, subject 4 recorded the greatest amount of time the COP was outside the BOS for configuration CTSD CG,

but had the least amount of total COP travel. Thus individual differences contribute a great amount to the results for stability and should be considered in future tests.

Several factors may have worked to confound the stability analysis results. As mentioned previously many subjects did not adhere to the rock pickup protocol. One subject dropped down to pick it up but just dropped the rock while standing instead of bending to set it down. Some subjects chose to step on to the force plates while also reaching forward for the rock, thus confounding the data. Stricter subject adherence to the testing protocol will only improve the quality of the results.

When the subjects were in the gimbal and suspended by the POGO, only one subject tried to continue the bending at the waist. Other subjects used a lunge technique, did not move the upper torso at all, or used the POGO uplift to assist the subject dropping or leaning in to get the rock. Constructing or using test hardware that will allow the subjects all the degrees of freedom afforded to them with no hardware attached may improve the results and inferences for this analysis.

On average, the shoveling task had much less percentage of time outside the BOS compared to the rock pick up. This is contrary to what would be expected. Shoveling requires more complex movements of coordinating upper and lower body. Each subject had difficulty with different configurations. There was not a clear trend across configurations. Only subject 3 performed each configuration consistently, but the rotation of the gimbal falling forward and the rig getting caught on the gimbal for only the Perfect CG configuration confounded the results.

No CG configuration clearly appeared to have greater stability than the others. For both the rock pick up and shoveling tasks, there was too much variability between the subjects and across the conditions to make any viable comparisons. Further, there were no observable trends for either task in any of the tested CG conditions. It is believed that this lack of finding is mostly due to the confounding interactions between the POGO, gimbal, CG rig, and subjects previously mentioned. Subject strength or lack thereof may also have played a role in the variability of the results.

5.2.3 Subjective Ratings

Subjective results further supported the negative impacts of the CTSD CG on human performance, but this finding was more likely due to system CG misalignment with the gimbal axes of rotation than system CG variation from the subject CG.

Beyond using the subjective ratings to compare different configurations, one surprising finding was the large amount of variation within the ratings at a given condition, most notably with the Backpack, CTSD, and POGO CGs. This highlights the great degree of variability that is present in the astronaut population. Future EVA systems tests should include a larger sample size and should not assume a reasonably homogenous astronaut population. Further, the subjects should be characterized with respect to anthropometry, strength, and fitness so that these measures can be considered during posttest analyses and explanations of results.

5.3 Postural Stability

While we set out to answer the question of which CG configuration(s) might have the least influence on postural stability control, to interpret our results, it was also necessary to determine whether the POGO system and/or offload affected postural stability control during the experiments. We also needed

to determine how the POGO system affected the subject body weight from condition to condition. We found that the weight was fairly well controlled throughout the experiments (Figure 4-66), that both the POGO system and the offload level affected postural stability, and that at least one CG configuration was very disruptive to postural stability control.

The test conditions employed were derived from measurements routinely used in clinical assessment of balance disorders (34) as well as in assessment of postflight recovery of neurological function in astronauts (35) (36) (37) (38). SOT 1 was selected as the best-case postural stability control condition, with full sensory system availability and no challenging environmental conditions. SOT 4 challenged the subjects' posture control systems by distorting somatosensory inputs in ways similar to what a crewmember might experience while standing (or walking) in a thick layer of regolith on the lunar surface. The perturbation trials examined the subjects' abilities to respond to sudden external challenges to postural stability in the forward (toes-down) or backward (toes-up) direction. Such perturbations could occur on the lunar surface by a sudden shift in the regolith or by being bumped by another crewmember.

The postural stability performance measures employed included the EQ score (34), which is a standard clinical measure that allowed comparison of performance results with a large extant database of normal test subject performance measured by JSC Neurosciences Laboratory personnel over the past 20 yr, and time-to-contact, a more robust measure that has become more widely used in the past 5 to 10 yr (39). EQ score is somewhat limited in that it is based on peak postural sway displacements over a 20-s period. TTC improves on this by adding information about sway velocity and extending analyses to the entire 100-s duration of the trial. We analyzed the TTC time series in terms comparable to the EQ score, the worst-case (minimum) value of TTC over the trial, as well as by integrating the total time during the trial the TTC was less than 10 s (an arbitrary cutoff value). EQ score and TTC_{min} indicate how close the subject came to losing balance during a trial (which could have been a singular event), while iTTC is a measure related to the total amount of time that the subject was at risk of losing balance during the trial, and it should be related to the amount of metabolic effort that subject had to put into maintaining upright stability during the trial.

We were unable to perform our planned statistical analysis because of the small number of subjects tested and relatively high variability of the dependent measure data. Thus, we recommend that future studies strive to recruit more test subjects. Nevertheless, qualitative assessments of these data provide some valuable insights into the general effects of the CG configurations under evaluation and the independent effects of the POGO system and the offload profile.

It appears from the EQ score data that postural stability during quiet stance was improved when the subject donned the POGO gimbal system and the system was activated to offload the weight of the gimbal structure (Figure 4-67, 1-g versus 1-g (Perfect)). This putative stability improvement was not observed for the two TTC indices because of increased variability (Figure 4-68 and Figure 4-69, 1-g versus 1-g [Perfect]), suggesting that the POGO system had a greater affect on sway displacements than sway velocities. Possible reasons for this putative stability improvement include: (1) an increased test subject vigilance caused by the perceived threat of falling while wearing the heavy, unwieldy gimbal system, (2) a mechanical stabilizing effect of the POGO system support device, and/or (3) new orientation information provided by the POGO force vector, perhaps similar to the posture stabilizing effect of light touch (40). For sudden postural perturbations the POGO system appeared to improve the worst-case stability (TTC_{min}; Figure 4-70) but degrade the overall postural stability performance (iTTC; Figure 4-71).

It appears from the SOT 1 quiet stance data that increasing the offload from body weight to 1/6 of body weight plus gimbal and CG rig weight degraded postural stability control (Figure 4-67 to Figure 4-69, top, 1-g (Perfect) versus Perfect), possibly related to an unappreciated decrease in the gain requirement for the control-system generating motor responses to counter postural balance errors detected by the visual, vestibular, and somatosensory systems or, alternatively, to a reduction in the sensitivity of the somatosensory detectors. However, as postural stability control was not affected in a similar way during the SOT 4 trials (Figure 4-67 to Figure 4-69, top, 1-g (Perfect) versus Perfect), in which somatosensory cues were purposefully distorted by the CDP system, it seems more likely that the reduced loading affected the sensory information available from the somatosensory system. If true, this could have significant implications to postural stability during lunar (and other hypogravity) EVA activities. For this reason, we recommend that this finding be investigated further, and we suggest that the best next step would be to use similar CDP paradigms to examine the postural stability control of test subjects exposed to intermittent hypogravity at different G-levels (0.17, 0.33, 0.5, etc.) during parabolic flight campaigns.

It appears that the CTSD configuration substantially degrades postural stability during quiet stance and in response to sudden unexpected postural perturbations. Wearing the CTSD configuration, some subjects lost balance or refused to attempt each test condition examined in this study. No other CG configuration stood out as having particularly positive or negative effects on postural stability control, although one subject refused to attempt the quiet stance tasks while in the POGO configuration, and at least one subject lost balance multiple times during toes-up rotations while in the Backpack configuration. Thus, the Perfect CG appears to have had the least effect on postural stability of the CG configurations tested.

5.4   Study Limitations

There were a number of limitations with this test. Given the biomechanical, physiological, and capability and strategy observations, the analyses suggest that some subjects may have been using the inherent POGO system mechanics to reduce their physical work load while ambulating. The data also suggests that the system (POGO, gimbal, and CG rig) may have greatly altered the gait mechanics of the subjects and restricted normal ranges of motion. The added inertia of the POGO pneumatic cylinder, gimbal, and the CG rig were large enough to cause impediments to the subjects while performing tasks. As a result, there is a significant need for an improved offload system, including improvements to the gimbal and CG rig that minimize altered inertial effects.

The POGO system also was found to have its own dynamics that influenced subjects during ambulation. These influences were observed as a lack of rigid attachment of the CG rig to the subject while ambulating. The POGO system was shown to lag slightly behind the subject during ambulation trials, creating a dynamic out-of-phase condition between the subject and the rest of the system. These two system characteristics created collisions between the subject and the CG rig, resulting in abnormal system CG variation during the ambulation trials. Abnormalities of this type are assumed to have influenced the kinetic, kinematic, and physiologic data collected.

Another limitation was that the CG locations were modeled based on a standard subject (182.9 cm, 81.6 kg) and as the tested subjects differed from this standard subject, the actual location of the system CG was affected. System CG locations varied by subject, but did not vary enough such that any one categorical CG location crossed into another CG category (Figure 4-1). Although each system CG was

slightly different from the model calculated system CG, they were still within a 2 cm radius of the model calculated system CG.

Of the 4 tested CG locations, the CTSD configuration led to increased metabolic rate, decreased postural stability and confounded some of the biomechanical markers. Posttest analyses indicated that this CG configuration was not properly aligned with the gimbal axes of rotation and placed subjects in a difficult position that many could not properly compensate for. Subjects felt as if they were being pulled down and backwards and this feeling was consistent with the analysis placing the CTSD system CG notably aft of the gimbal axes of rotation (Figure 4-2).

Although many IST team members agree with the previous theory that the CTSD CG condition led to poor performance because the system CG was misaligned with gimbal axes of rotation, there was a contrasting point of view from the ABF. Based on their biomechanical analysis, there was minimal variation seen among the different CG locations. The ABF asserts that this may be because the gimbal rotational axes were co-located with the system CG locations. Their hypothesis is that as the system was offloaded by 83% of the total system 1-g weight, the gimbal axes became the major pivot point for the human torso, thus reducing the differences that would be felt by the subject. It is the ABF's position that, due to this alignment, the full difference in moment arms of changing CG locations was not realized.

A significant issue with attempting to co-locate the gimbal axes of rotations with the subject's major pivot point, ie, the hips, would be that the system CG would then be aft and above the gimbal axes of rotation and could lead to many of the same problems seen with the CTSD CG. Without further testing with an improved offload system and gimbal that minimize added rotational and translational inertia, it will be impossible to determine the separate effects of gimbal/CG misalignment.

5.5   Lessons Learned

It is clear that studying varied CG locations by using overhead suspension has limitations and unanswered questions. These include where to properly align the gimbal axes of rotation (subject hips or system CG), how to add enough mass to vary CG without overwhelming the moments of inertia and compromising normal human movement, and how to account for 2 potential sources of stability (feet and overhead lift vector). To properly evaluate varied CG using overhead suspension several things will need to be improved. These include:

1. Decreasing the overall mass and moment of inertia of the gimbal support structure and additional CG rig components
2. Designing a gimbal that would provide adjustability needed to either co-locate the gimbal axes of rotation with the subject's hips or with the system CG
3. Designing a CG rig that does not require long horizontal arms that impede the subject's workspace
4. Providing translational freedom in both the X and Y axes
5. Reducing mass and moment of inertia in the overhead lift system
6. Providing active control of the overhead lift column in both the X and Y translational axes

Exploration tasks were not performed in as EVA-like manner as possible. This was due to the long horizontal arms of the CG rig and a desire to use similar methodology to other tests (2). All future tests

should attempt to test in the most EVA similar manner as possible and then only modify if necessary and provide the rationale for the modification.

Initially, it was thought that changing between all 4 CG configurations would be too difficult within the same test session. Although somewhat more burdensome, it was possible and would have allowed all level ambulation trials at each CG condition to be performed on 1 day and all incline ambulation trials at each CG condition to be performed on a different day, rather than mixing level and incline trials and limiting sessions to only 2 CG configurations on any test day. This would potentially lead to a better ability to subjectively compare and provide feedback among different CG conditions because the tasks would be the same on the same day for all 4 CG conditions.

6   Summary

6.1   Metabolic Rate

The only CG that resulted in significant metabolic differences was the CTSD configuration. All other varied CG configurations unexpectedly showed almost identical metabolic values. The variation in the CTSD configuration was likely due to system configuration issues and not because it was a poor CG location. Overall, the lack of variability among the other three CG configurations indicates that either there was no notable difference in human performance among these CG configurations or there were factors that compromised the ability to effectively vary CG using an overhead suspension lunar gravity simulator. Possible solutions to this question were discussed in the Lessons Learned section.

6.2   Biomechanics

There were no meaningful changes seen between the differing CG conditions. There were some differences seen between one of the CG locations and the other three locations, but the data analysis lead us to believe the difference was a result of the system dynamics, hardware setup, and testing methodology, not as a direct result of the system CG location in relation to the subject's CG.

6.3   Subjective Ratings

Results between CG conditions for ambulation were very similar to the metabolic results and lead to similar conclusions. Findings of greater importance were the high degree of variability for subjective ratings between subjects for the exploration tasks and postural control tests. This highlights the need to test a greater number of subjects and to thoroughly characterize the subject pool so that aspects of their anthropometry, strength, and/or fitness can be analyzed to determine if these underlying subject characteristics had a significant effect on their performance.

In addition to the standard end of trial assessment of RPE and GCPS, subjects were also assessed at the 30-s mark shortly after each trial began. Results indicated that GCPS had less variability between the early and end of trial measurements, with 82% of trials showing no change. RPE had more variability, but still 68% of trials did not change from initial to end of trial rating. The vast majority of the RPE and GCPS results that did change increased by 1 unit (26% for RPE, 12% for GCPS). Although not conclusive, it does show promise for using both of these ratings in non steady state tasks, especially in environments that preclude metabolic measurement.

RPE was rated differently in the 1-g no rig setting than in all other settings involving the CG rig. This is a similar finding to how suited and unsuited subjects rate RPE differently (5) (1). In a model using RPE and GCPS to predict metabolic rate, both were significant predictors with RPE driving the model and GCPS providing the fine tuning that has been a consistent finding with other studies (5) (1).

6.4 Postural Control

The POGO system provides a reasonable ground-based analog for testing postural stability during reduced-gravity loading; however, its mechanical couplings limit observations to a single plane of motion (sagittal in this case) and its upward force vector may have a mechanical and/or physiologic (haptic) stabilizing influence on balance control that could reduce apparent instabilities, particularly in body sway displacement.

Postural stability appeared to be degraded during the simulated reduced-gravity loading conditions tested in this experiment, and the performance patterns suggest that somatosensory information may be degraded in hypogravity environments. This finding has significant implications regarding the fall incidence observed during Apollo surface operations and those that should be anticipated during future exploration missions, regardless of suit design constraints. We recommend that follow-up experiments be performed, probably during parabolic flight, to verify these findings without the potential mechanical confounds of the POGO system.

Comparisons among the four CG configurations tested show that the CTSD CG created far greater disruptions to postural stability than any of the others, likely due to the misalignment issues rather than implying that an EVA suit having this CG configuration would result in more falls and higher metabolic effort than one having any of the other CG configuration tested. Differences between the other CG configurations were more difficult to discern; however, the Perfect configuration appeared to have the smallest effect on postural stability as assessed by this experiment.

The small number of subjects tested and the relatively high variability of the dependent measures limited our ability to perform statistical analyses. Thus, these conclusions are based on subjective interpretation of our results, and further study would be required to provide conclusions that may assist in finalizing an optimal CG design location.

Figure A-1. Commonly used biomechanics nomenclature of the body planes, the types of joint motion, and the body-based directions.
Figure A-2. Designations for the ankle joint directional rotations.
Figure A-3. Convention for local reference frames as prescribed by the International Society of Biomechanics and used by the ABF (4). The y-axis usually lies along the long axis of the segment.
Figure A-4. Flexion is termed as the decrease in the relative angle between two segments. Flexion/dorsiflexion of a joint will always be a positive rotation in this report.

Appendix B: Subjective Ratings Scales

Gravity Compensation and Performance Scale

1	**Excellent** – easier than 1-g
2	**Good** – equivalent to 1-g
3	**Fair** – minimal compensation for desired performance
4	**Minor** – moderate compensation for desired performance
5	**Moderately objectionable** – considerable compensation for adequate performance
6	**Very objectionable** – extensive compensation for adequate performance
7	**Major deficiencies** – considerable compensation for control, performance compromised
8	**Major deficiencies** – intense compensation, performance compromised
9	**Major deficiencies** – adequate performance not attainable with maximum tolerable compensation
10	**Major deficiencies** – unable to perform task

Borg Rating of Perceived Exertion Scale (RPE)

6	No exertion at all
7	Extremely light
8	
9	Very light

-1	A Bit Warmer
0	No Change
1	A Bit Cooler
2	Much Cooler

Appendix C: Treadmill Relative Velocity

In normal, stationary reference frame environments, vertical and horizontal velocities determine the distance traveled (Figure C-1). On a treadmill the reference frame is moving, so from an external observer, the trajectory will be elongated as a function of the reference frame velocity (Figure C-2). Equations C1 and C2 show the basic equations used for trajectory motion for a ballistic body.

For vertical motion in the y direction:

$$y = v_{0y}t - \frac{1}{2}gt^2$$

(Equation C1)

For horizontal motion in the x direction:

$$x = v_{0x}t$$

(Equation C2)

Over-ground Trajectories
Figure C-1. Visual representation of trajectory motion with a stationary reference frame.

126
Figure C-2. Visual representation of a trajectory with and without a moving reference frame. The blue line represents the relative trajectory from the ballistic velocities, as seen from the moving coordinate system; the black line represents the trajectory as seen from an outside observer.

Appendix D: List of Variables for Common Equations and Relationships

Linear Motion

Position: x

Velocity: v

Acceleration: a

Mass: m

Force: ma

Work: Fd

Kinetic Energy: $\frac{1}{2} mv^2$

Power: Fv

Rotational Motion

Angular Position: θ

Angular Velocity: ω

Angular Acceleration: α

Moment of Inertia: I

Moment/Torque: $I\alpha, \tau$

Work: $\tau\theta$

Kinetic Energy: $\frac{1}{2} I\omega^2$

Power: $\tau\omega$

Per the NASA Constellation Interoperability Standards (CxP 70022-04) document, the units expressed in this report are in standard SI units. The following conversions to English units are given:

Mass:	1 kg	=	2.204 lbm
Force:	1 N	=	0.225 lb
Speed:	1 m/s	=	2.237 mph
Pressure:	1 kPa	=	0.145 psi

Figure E- 2. Muscle activation of the erector spinae at 0.8 m·s⁻¹ for all CG configurations and with no rig at 1-g.
Figure E- 3. Muscle activation of the erector spinae at 1.3 m·s⁻¹ for all CG configurations and with no rig at 1-g.
Figure E- 4. Muscle activation of the erector spinae at 1.7 m·s⁻¹ for all CG configurations and with no rig at 1-g.
Figure E- 5. Muscle activation of the erector spinae at 2.1 m·s⁻¹ for all CG configurations and with no rig at 1-g.
Figure E- 6. Muscle activation of the erector spinae at 2.5 m·s⁻¹ for all CG configurations and with no rig at 1-g.
Figure E- 7. Muscle activation of the erector spinae at -10% grade for all CG configurations and with no rig at 1-g.
Figure E- 8. Muscle activation of the erector spinae at 0% grade for all CG configurations and with no rig at 1-g.
Figure E- 9. Muscle activation of the erector spinae at 10% grade for all CG configurations and with no rig at 1-g.

**Figure E- 10. Muscle activation of the erector spinae at 20% grade for all CG configurations and with no rig at 1-g.**
Figure E- 11. Muscle activation of the erector spinae at 30% grade for all CG configurations and with no rig at 1-g.

Appendix F: Test Termination Criteria

<u>Test Termination Criteria for All Sub-maximal Testing:</u>

- Subject request to stop at any time
- Subject's heart rate or measured VO_2 at level > 85% VO_2pk or 85% of age predicted heart rate max (if no recent VO_2pk test on file) for 2 min or more
- If subject reports discomfort rating > 7 (on Corlett and Bishop 10-point Discomfort scale) for two consecutive recording periods, subject will be asked to terminate the test.
- Subject reports discomfort rating of 10
- Failure of POGO hardware and/or treadmill system

<u>Test Termination Criteria for Postural Stability:</u>

- Subject request to stop at any time
- Syncope or significant dizziness
- Subject reports persistent pain or discomfort
- Injury due to a fall

Appendix G: IST-3 Test Conductor Checklist

CxP EVA Systems Test 3 - Shirt Sleeve Test Session 1 Checklist

Setup:
- ☐ 1) Ensure subject's clothes and shoes are ready
- ☐ 2) Determine and record the randomized order to be used for the days trials (EPSP)
- ☐ 3) Prepare data sheets for test session (EPSP)
- ☐ 4) Ensure medical monitor is identified (EPSP)
- ☐ 5) Prepare and calibrate met cart (EXL)
- ☐ 6) Prepare and calibrate NIRS (EXL)
- ☐ 7) Prepare & calibrate motion capture system for subject (ABF)
- ☐ 8) Prepare & calibrate ground reaction force system (ABF)
- ☐ 9) Prepare shirtsleeve rig for initial condition (EPSP)

Pre-Test Preparation:
- ☐ 1) Have subject read and sign informed consent form, w/ test conductor answering questions
- ☐ 2) Ask subject to enter the changing area
- ☐ 3) Provide subject clothing and heart rate strap - explain donning order
- ☐ 4) Instrument subject with EMG system and remaining clothes
- ☐ 5) Ask subject to don the form fitting suit and shoes for motion capture
- ☐ 6) Weigh subject
- ☐ 7) Describe the test procedure and familiarize the subject with the shirtsleeve rig
- ☐ 8) Go over Cooper-Harper, RPE, and Thermal ratings with subject (UTAF)

Pre-Test Briefing
- ☐ 1) Hand out data/cover sheet with test order and objectives
- ☐ 2) Review motion capture field
- ☐ 3) Review hard hat area
- ☐ 4) Medical monitor identified and contact information posted
- ☐ 5) Test termination criteria reviewed and posted
- ☐ 6) Emergency egress procedures reviewed and personnel identified

Trial 1 Preparation - Level Treadmill:
- ☐ 1) Instrument subject with reflective markers for motion capture
- ☐ 2) Instrument subject with NIRS
- ☐ 3) Instrument subject with Cosmed
- ☐ 5) Assist subject onto center of treadmill
- ☐ 6) Have subject stand still for approx. 10 seconds for static shot and weight capture
- ☐ 7) Check EMG system (ABF)

Trial 1 Steps - Level Treadmill

- ☐ 1) Ensure all teams are ready and metabolic rate is being captured
- ☐ 2) Inform test subject that the treadmill is starting and increase to 0.9 mph
- ☐ 3) Based on Cosmed clock, start the actual data collection on the minute or half minute
- ☐ 4) UTAF to record RPE and GCPS at 30 sec
- ☐ 5) ABF to record kinetic/kinematic data for 30 strides immediately after UTAF
- ☐ 6) UTAF to record RPE, GCPS, Discomfort and Thermal Comfort within last 30 sec of 3 min
- ☐ 7) Increase speed to 1.9 mph and repeat steps 4-6
- ☐ 8) Increase speed to 2.8 mph and repeat steps 4-6
- ☐ 9) Increase speed to 3.7 mph and repeat steps 4-6
- ☐ 10) Increase speed to 4.6 mph and repeat steps 4-6
- ☐ 11) Increase speed to 5.6 mph and repeat steps 4-6
- ☐ 12) Inform test subject that the treadmill is stopping and stop treadmill
- ☐ 13) Help subject off treadmill and provide a seat
- ☐ 14) Offer subject water as needed

Trial 2 Preparation - Incline/Decline Treadmill

- ☐ 1) Check and reinstrument subject with reflective markers as needed
- ☐ 2) Check NIRS
- ☐ 3) Instrument subject with Cosmed
- ☐ 4) Assist subject onto center of treadmill
- ☐ 5) Have Subject stand still for approx. 10 seconds for static shot and weight capture
- ☐ 6) Help subject off treadmill and adjust to -10%
- ☐ 7) Check EMG system (ABF)

Trial 2 Steps - Incline/Decline Treadmill

- ☐ 1) ABF measures treadmill orientation data at -10%
- ☐ 2) Assist subject onto center of treadmill
- ☐ 3) Ensure all teams are ready and metabolic rate is being captured
- ☐ 4) Inform test subject that the treadmill is starting and increase to 1.9 mph
- ☐ 5) Based on the Cosmed clock, start the actual data collection on the minute or half minute
- ☐ 6) UTAF to record RPE and GCPS @ 30 sec
- ☐ 7) ABF to record kinetic/kinematic data for 30 strides immediately after UTAF
- ☐ 8) UTAF to record RPE, GCPS, discomfort, and Thermal comfort within last 30 sec of 3 min
- ☐ 9) At 3 min, stop treadmill and help subject off of treadmill
- ☐ 10) Increase incline to 10% and repeat steps 1-9
- ☐ 11) Increase incline to 20% and repeat steps 1-9
- ☐ 12) Increase incline to 30% and repeat steps 1-9
- ☐ 13) Remove Cosmed and recalibrate, also download Cosmed data

- ☐ 14) Return Treadmill to 0%
- ☐ 15) Offer subject water as needed

Trial 3 Preparation - Level Treadmill:

- ☐ 1) Offload CG rig to neutral
- ☐ 2) Assist subject in getting into the shirtsleeve rig harness while attached to the Pogo
- ☐ 3) Instrument subject with reflective markers for motion capture
- ☐ 4) Instrument subject with NIRS
- ☐ 5) Instrument subject with Cosmed
- ☐ 6) Offload subject to approximate target weight
- ☐ 7) Subject stands on scale
- ☐ 8) Adjust to target weight and record weight
- ☐ 9) Assist subject onto center of treadmill
- ☐ 10) Have subject stand still for approx. 10 seconds for static shot and weight capture
- ☐ 11) Check EMG system (ABF)

Trial 3 Steps - Level Treadmill

- ☐ 1) Ensure all teams are ready and metabolic rate is being captured
- ☐ 2) Inform test subject that the treadmill is starting and increase to 0.9 mph
- ☐ 3) Based on Cosmed clock, start the actual data collection on the minute or half minute
- ☐ 4) UTAF to record RPE and GCPS at 30 sec
- ☐ 5) ABF to record kinetic/kinematic data for 30 strides immediately after UTAF
- ☐ 6) UTAF to record RPE, GCPS, Discomfort and Thermal Comfort within last 30 sec of 3 min
- ☐ 7) Increase speed to 1.9 mph and repeat steps 4-6
- ☐ 8) Increase speed to 2.8 mph and repeat steps 4-6
- ☐ 9) Increase speed to 3.7 mph and repeat steps 4-6
- ☐ 10) Increase speed to 4.6 mph and repeat steps 4-6
- ☐ 11) Increase speed to 5.6 mph and repeat steps 4-6
- ☐ 12) Inform test subject that the treadmill is stopping and stop treadmill
- ☐ 13) Help subject off treadmill and provide a seat
- ☐ 14) Reduce offload to CG rig neutral
- ☐ 15) Remove Cosmed and download data

Trial 4 Preparation - Incline/Decline Treadmill

- ☐ 1) Check and reinstrument subject with reflective markers as needed
- ☐ 2) Check NIRS
- ☐ 3) Instrument subject with Cosmed
- ☐ 4) Offload subject to approximate target weight
- ☐ 5) Subject stands on scale
- ☐ 6) Adjust to target weight and record weight

- ☐ 7) Assist subject onto center of treadmill
- ☐ 8) Have Subject stand still for approx. 10 seconds for static shot and weight capture
- ☐ 9) Help subject off treadmill and adjust to -10%
- ☐ 10) Check EMG system (ABF)

Trial 4 Steps - Incline/Decline Treadmill

- ☐ 1) ABF measures treadmill orientation data at -10%
- ☐ 2) Assist subject onto center of treadmill
- ☐ 3) Ensure all teams are ready and metabolic rate is being captured
- ☐ 4) Inform test subject that the treadmill is starting and increase to 1.9 mph
- ☐ 5) Based on the Cosmed clock, start the actual data collection on the minute or half minute
- ☐ 6) UTAF to record RPE and GCPS @ 30 sec
- ☐ 7) ABF to record kinetic/kinematic data for 30 strides immediately after UTAF
- ☐ 8) UTAF to record RPE, GCPS, discomfort, and Thermal comfort within last 30 sec of 3 min
- ☐ 9) At 3 min, stop treadmill and help subject off of treadmill
- ☐ 10) Increase incline to 10% and repeat steps 1-9
- ☐ 11) Increase incline to 20% and repeat steps 1-9
- ☐ 12) Increase incline to 30% and repeat steps 1-9
- ☐ 13) Reduce offload to CG rig neutral and provide a seat
- ☐ 14) Remove Cosmed and download Cosmed data
- ☐ 15) Return Treadmill to 0%

Trial 5 Preparation - Level Treadmill

- ☐ 1) Adjust CG rig to new CG setting as described in test randomization order
- ☐ 2) Check and reinstrument subject with reflective markers as needed
- ☐ 3) Check NIRS
- ☐ 4) Instrument subject with Cosmed
- ☐ 5) Offload subject to approximate target weight
- ☐ 6) Subject stands on scale
- ☐ 7) Adjust to target weight and record weight
- ☐ 8) Assist subject onto center of treadmill
- ☐ 9) Have Subject stand still for approx. 10 seconds for static shot and weight capture
- ☐ 11) Check EMG system (ABF)

Trial 5 Steps - Level Treadmill

- ☐ 1) Assist subject onto center of treadmill
- ☐ 2) Ensure all teams are ready and metabolic rate is being captured
- ☐ 3) Inform test subject that the treadmill is starting and increase to 1.9 mph
- ☐ 4) Based on the Cosmed clock, start the actual data collection on the minute or half minute
- ☐ 5) UTAF to record RPE and GCPS @ 30 sec

☐ 6) ABF to record kinetic/kinematic data for 30 strides immediately after UTAF

☐ 7) UTAF to record RPE, GCPS, discomfort, and Thermal comfort within last 30 sec of 3 min

☐ 8) Increase speed to 1.9 mph and repeat steps 6-8

☐ 9) Increase speed to 2.8 mph and repeat steps 6-8

☐ 10) Increase speed to 3.7 mph and repeat steps 6-8

☐ 11) Increase speed to 4.6 mph and repeat steps 6-8

☐ 12) Increase speed to 5.6 mph and repeat steps 6-8

☐ 13) Inform test subject that the treadmill is stopping and stop treadmill

☐ 14) Help subject off of treadmill

☐ 15) Reduce offload to CG rig neutral and provide a seat

☐ 16) Remove Cosmed and download Cosmed data

Trial 6 Preparation - Incline/Decline Treadmill

☐ 1) Check and reinstrument subject with reflective markers as needed

☐ 2) Check NIRS

☐ 3) Instrument subject with Cosmed

☐ 4) Offload subject to approximate target weight

☐ 5) Subject stands on scale

☐ 6) Adjust to target weight and record weight

☐ 7) Assist subject onto center of treadmill

☐ 8) Have Subject stand still for approx. 10 seconds for static shot and weight capture

☐ 9) Help subject off treadmill and adjust to -10%

☐ 10) Check EMG system (ABF)

Trial 6 Steps - Incline/Decline Treadmill

☐ 1) ABF measures treadmill orientation data at -10%

☐ 2) Assist subject onto center of treadmill

☐ 3) Ensure all teams are ready and metabolic rate is being captured

☐ 4) Inform test subject that the treadmill is starting and increase to 1.9 mph

☐ 5) Based on the Cosmed clock, start the actual data collection on the minute or half minute

☐ 6) UTAF to record RPE and GCPS @ 30 sec

☐ 7) ABF to record kinetic/kinematic data for 30 strides immediately after UTAF

☐ 8) UTAF to record RPE, GCPS, discomfort, and Thermal comfort within last 30 sec of 3 min

☐ 9) At 3 min, stop treadmill and help subject off of treadmill

☐ 10) Increase incline to 10% and repeat steps 1-9

☐ 11) Increase incline to 20% and repeat steps 1-9

☐ 12) Increase incline to 30% and repeat steps 1-9

☐ 13) Reduce offload to CG rig neutral and provide a seat

☐ 14) Remove Cosmed and download Cosmed data

☐ 15) Return Treadmill to 0%

Test Completion & Cleanup:

☐ 1) Collect and properly secure met cart data for subject

☐ 2) Collect and properly secure motion capture data for subject

☐ 3) Collect and properly secure ground reaction force data for subject

☐ 4) Collect and properly secure Pogo data for subject

☐ 5) Clean met cart equipment, including sterilization of nose clip & mouthpiece

☐ 6) Clean and power down all equipment as necessary

CxP EVA Systems Test 3 - Shirt Sleeve Test Session 2 Checklist

Setup:

- ☐ 1) Ensure subject's clothes and shoes are ready
- ☐ 2) Determine and record the randomized order to be used for the days trials (EPSP)
- ☐ 3) Prepare data sheets for test session (EPSP)
- ☐ 4) Ensure medical monitor is identified (EPSP)
- ☐ 5) Prepare and calibrate met cart (EXL)
- ☐ 6) Prepare & calibrate motion capture system for subject (ABF)
- ☐ 7) Prepare & calibrate ground reaction force system (ABF)
- ☐ 8) Prepare shirtsleeve rig for initial condition (EPSP)

Pre-Test Preparation:

- ☐ 1) Have subject read and sign informed consent form, w/ test conductor answering questions
- ☐ 2) Ask subject to enter the changing area and record their naked body weight
- ☐ 3) Provide subject clothing and heart rate strap - explain donning order
- ☐ 4) Instrument subject with EMG system and remaining clothes
- ☐ 5) Ask subject to don the form fitting suit for motion capture
- ☐ 6) Describe the test procedure and familiarize the subject with the shirtsleeve rig

Pre-Test Briefing

- ☐ 1) Hand out data/cover sheet with test order and objectives
- ☐ 2) Review motion capture field
- ☐ 3) Review hard hat area
- ☐ 4) Medical monitor identified and contact information posted
- ☐ 5) Test termination criteria reviewed and posted
- ☐ 6) Emergency egress procedures reviewed and personnel identified

Trial 1 Preparation - Level Treadmill:

- ☐ 1) Offload CG rig to neutral
- ☐ 2) Assist subject in getting into the shirtsleeve rig harness while attached to the Pogo
- ☐ 3) Instrument subject with reflective markers for motion capture
- ☐ 4) Instrument subject with NIRS
- ☐ 5) Instrument subject with Cosmed
- ☐ 6) Offload subject to approximate target weight
- ☐ 7) Subject stands on scale
- ☐ 8) Adjust to target weight and record weight
- ☐ 9) Assist subject onto center of treadmill
- ☐ 10) Have subject stand still for approx. 10 seconds for static shot and weight capture
- ☐ 11) Check EMG system (ABF)

Trial 1 Steps - Level Treadmill

☐ 1) Ensure all teams are ready and metabolic rate is being captured

☐ 2) Inform test subject that the treadmill is starting and increase to 0.9 mph

☐ 3) Based on Cosmed clock, start the actual data collection on the minute or half minute

☐ 4) UTAF to record RPE and GCPS at 30 sec

☐ 5) ABF to record kinetic/kinematic data for 30 strides immediately after UTAF

☐ 6) UTAF to record RPE, GCPS, Discomfort and Thermal Comfort within last 30 sec of 3 min

☐ 7) Increase speed to 1.9 mph and repeat steps 4-6

☐ 8) Increase speed to 2.8 mph and repeat steps 4-6

☐ 9) Increase speed to 3.7 mph and repeat steps 4-6

☐ 10) Increase speed to 4.6 mph and repeat steps 4-6

☐ 11) Increase speed to 5.6 mph and repeat steps 4-6

☐ 12) Inform test subject that the treadmill is stopping and stop treadmill

☐ 13) Help subject off treadmill and provide a seat

☐ 14) Reduce offload to CG rig neutral

☐ 15) Remove Cosmed and download data

Trial 2 Preparation - Incline/Decline Treadmill

☐ 1) Check and reinstrument subject with reflective markers as needed

☐ 2) Check NIRS

☐ 3) Instrument subject with Cosmed

☐ 4) Offload subject to approximate target weight

☐ 5) Subject stands on scale

☐ 6) Adjust to target weight and record weight

☐ 7) Assist subject onto center of treadmill

☐ 8) Have Subject stand still for approx. 10 seconds for static shot and weight capture

☐ 9) Help subject off treadmill and adjust to -10%

☐ 10) Check EMG system (ABF)

Trial 2 Steps - Incline/Decline Treadmill

☐ 1) ABF measures treadmill orientation data at -10%

☐ 2) Assist subject onto center of treadmill

☐ 3) Ensure all teams are ready and metabolic rate is being captured

☐ 4) Inform test subject that the treadmill is starting and increase to 1.9 mph

☐ 5) Based on the Cosmed clock, start the actual data collection on the minute or half minute

☐ 6) UTAF to record RPE and GCPS @ 30 sec

☐ 7) ABF to record kinetic/kinematic data for 30 strides immediately after UTAF

☐ 8) UTAF to record RPE, GCPS, discomfort, and Thermal comfort within last 30 sec of 3 min

☐ 9) At 3 min, stop treadmill and help subject off of treadmill

- ☐ 10) Increase incline to 10% and repeat steps 1-9
- ☐ 11) Increase incline to 20% and repeat steps 1-9
- ☐ 12) Increase incline to 30% and repeat steps 1-9
- ☐ 13) Reduce offload to CG rig neutral and provide a seat
- ☐ 14) Remove Cosmed and download Cosmed data
- ☐ 15) Return Treadmill to 0%

Trial 3 Preparation - Level Treadmill

- ☐ 1) Adjust CG rig to new CG setting as described in test randomization order
- ☐ 2) Check and reinstrument subject with reflective markers as needed
- ☐ 3) Check NIRS
- ☐ 4) Instrument subject with Cosmed
- ☐ 5) Offload subject to approximate target weight
- ☐ 6) Subject stands on scale
- ☐ 7) Adjust to target weight and record weight
- ☐ 8) Assist subject onto center of treadmill
- ☐ 9) Have Subject stand still for approx. 10 seconds for static shot and weight capture
- ☐ 11) Check EMG system (ABF)

Trial 3 Steps - Level Treadmill

- ☐ 1) Assist subject onto center of treadmill
- ☐ 2) Ensure all teams are ready and metabolic rate is being captured
- ☐ 3) Inform test subject that the treadmill is starting and increase to 1.9 mph
- ☐ 4) Based on the Cosmed clock, start the actual data collection on the minute or half minute
- ☐ 5) UTAF to record RPE and GCPS @ 30 sec
- ☐ 6) ABF to record kinetic/kinematic data for 30 strides immediately after UTAF
- ☐ 7) UTAF to record RPE, GCPS, discomfort, and Thermal comfort within last 30 sec of 3 min
- ☐ 8) Increase speed to 1.9 mph and repeat steps 6-8
- ☐ 9) Increase speed to 2.8 mph and repeat steps 6-8
- ☐ 10) Increase speed to 3.7 mph and repeat steps 6-8
- ☐ 11) Increase speed to 4.6 mph and repeat steps 6-8
- ☐ 12) Increase speed to 5.6 mph and repeat steps 6-8
- ☐ 13) Inform test subject that the treadmill is stopping and stop treadmill
- ☐ 14) Help subject off of treadmill
- ☐ 15) Reduce offload to CG rig neutral and provide a seat
- ☐ 16) Remove Cosmed and download Cosmed data

Trial 4 Preparation - Incline/Decline Treadmill

- ☐ 1) Check and reinstrument subject with reflective markers as needed
- ☐ 2) Check NIRS

- ☐ 3) Instrument subject with Cosmed
- ☐ 4) Offload subject to approximate target weight
- ☐ 5) Subject stands on scale
- ☐ 6) Adjust to target weight and record weight
- ☐ 7) Assist subject onto center of treadmill
- ☐ 8) Have Subject stand still for approx. 10 seconds for static shot and weight capture
- ☐ 9) Help subject off treadmill and adjust to -10%
- ☐ 10) Check EMG system (ABF)

Trial 4 Steps - Incline/Decline Treadmill

- ☐ 1) ABF measures treadmill orientation data at -10%
- ☐ 2) Assist subject onto center of treadmill
- ☐ 3) Ensure all teams are ready and metabolic rate is being captured
- ☐ 4) Inform test subject that the treadmill is starting and increase to 1.9 mph
- ☐ 5) Based on the Cosmed clock, start the actual data collection on the minute or half minute
- ☐ 6) UTAF to record RPE and GCPS @ 30 sec
- ☐ 7) ABF to record kinetic/kinematic data for 30 strides immediately after UTAF
- ☐ 8) UTAF to record RPE, GCPS, discomfort, and Thermal comfort within last 30 sec of 3 min
- ☐ 9) At 3 min, stop treadmill and help subject off of treadmill
- ☐ 10) Increase incline to 10% and repeat steps 1-9
- ☐ 11) Increase incline to 20% and repeat steps 1-9
- ☐ 12) Increase incline to 30% and repeat steps 1-9
- ☐ 13) Reduce offload to CG rig neutral and provide a seat
- ☐ 14) Remove Cosmed and download Cosmed data
- ☐ 15) Return Treadmill to 0%

Test Completion & Cleanup:

- ☐ 1) Collect and properly secure met cart data for subject
- ☐ 2) Collect and properly secure motion capture data for subject
- ☐ 3) Collect and properly secure ground reaction force data for subject
- ☐ 4) Collect and properly secure Pogo data for subject
- ☐ 5) Clean met cart equipment, including sterilization of nose clip & mouthpiece
- ☐ 6) Clean and power down all equipment as necessary

CxP EVA Systems Test 3 - Postural Stability & Exp. Task Checklist

Setup:

- ☐ 1) Ensure subject's clothes and shoes are ready
- ☐ 2) Determine and record the randomized order to be used for the days trials (EPSP)
- ☐ 3) Prepare data sheets for test session (EPSP)
- ☐ 4) Ensure medical monitor is identified (EPSP)
- ☐ 5) Prepare & calibrate postural stability system (Neuro)
- ☐ 6) Prepare & calibrate motion capture system for subject (ABF)
- ☐ 7) Prepare & calibrate ground reaction force system (ABF)
- ☐ 8) Prepare shirtsleeve rig for initial condition (EPSP)
- ☐ 9) Prepare exploration task hardware (EPSP)

Pre-Test Preparation:

- ☐ 1) Describe the test procedure and familiarize the subject with the shirtsleeve rig
- ☐ 2) Ask subject to enter the changing area
- ☐ 3) Provide subject clothing and heart rate strap - explain donning order
- ☐ 4) Weigh and record subject weight

Pre-Test Briefing

- ☐ 1) Hand out data/cover sheet with test order and objectives
- ☐ 2) Review motion capture field
- ☐ 3) Review hard hat area
- ☐ 4) Medical monitor identified and contact information posted
- ☐ 5) Test termination criteria reviewed and posted
- ☐ 6) Emergency egress procedures reviewed and personnel identified

Trial 1 Preparation - Postural Stability and Exploration Tasks

- ☐ 1) Instrument subject with reflective markers for motion capture
- ☐ 2) Assist subject onto posture platform with proper foot placement

Trial 1 Steps - Postural Stability and Exploration Tasks

- ☐ 1) Inform test subject that the postural test is starting and complete 100 sec SOT 1 baseline trial
- ☐ 2) UTAF to record RPE and GCPS at trial completion
- ☐ 3) Inform test subject that the postural test is starting and complete 100 sec SOT 4 baseline trial
- ☐ 4) UTAF to record RPE and GCPS at trial completion
- ☐ 5) Inform test subject that the postural test is starting and complete 6x10 sec toes up/down trials
- ☐ 6) UTAF to record RPE and GCPS at trial completion
- ☐ 7) Move subject to rock pick-up area
- ☐ 8) On the ABF's signal, subject completes 3x rock pick up task

- [ ] 9) UTAF to record RPE and GCPS at trial completion
- [ ] 10) Switch shovel platform in for rock pick-up
- [ ] 11) On the ABF's signal, subject completes 3x shoveling task
- [ ] 12) UTAF to record RPE and GCPS at trial completion and then move subject to open area
- [ ] 13) On the ABF's signal, subject completes 3x kneel and recover task
- [ ] 14) UTAF to record RPE and GCPS at trial completion
- [ ] 15) Subject rests

Trial 2-6 Preparation - Postural Stability and Exploration Tasks

- [ ] 1) Help subject don adjustable CG rig
- [ ] 2) Instrument subject with reflective markers for motion capture
- [ ] 3) Adjust subject to correct offload
- [ ] 4) Assist subject onto posture platform with proper foot placement

Trial 2 Steps - Postural Stability and Exploration Tasks

- [ ] 1) Inform test subject that the postural test is starting and complete 100 sec SOT 1 baseline trial
- [ ] 2) UTAF to record RPE and GCPS at trial completion
- [ ] 3) Inform test subject that the postural test is starting and complete 100 sec SOT 4 baseline trial
- [ ] 4) UTAF to record RPE and GCPS at trial completion
- [ ] 5) Inform test subject that the postural test is starting and complete 6x10 sec toes up/down trials
- [ ] 6) UTAF to record RPE and GCPS at trial completion
- [ ] 7) Move subject to rock pick-up area
- [ ] 8) On the ABF's signal, subject completes 3x rock pick up task
- [ ] 9) UTAF to record RPE and GCPS at trial completion
- [ ] 10) Switch shovel platform in for rock pick-up
- [ ] 11) On the ABF's signal, subject completes 3x shoveling task
- [ ] 12) UTAF to record RPE and GCPS at trial completion and then move subject to open area
- [ ] 13) On the ABF's signal, subject completes 3x kneel and recover task
- [ ] 14) UTAF to record RPE and GCPS at trial completion
- [ ] 15) Subject rests and offload is removed
- [ ] 16) CG rig is adjusted and subject is assisted onto posture platform with proper foot placement
- [ ] 17) Steps 1-16 are repeated until all configurations are tested
